Executive Summary

The registration of new wood preservatives for H3 (outdoor above-ground) requires efficacy data from field tests, and comparisons can be made with established reference preservatives when the quarter-H3 reference preservative (usually CCA) reaches less than 70% mean soundness. Currently, even in the wet tropics, it can take seven years before there has been sufficient decay to allow comparisons, which stifles innovation. The objective of this project was to find a faster and more reliable above-ground H3 test method. The trial was installed at five sites (three in Australia, two in New Zealand), where two of the 'sites' were in Accelerated Field Simulators (AFSs). Twelve test methods were examined, some established and others developed for the project. Some methods had specimens placed near-to-ground while others were raised on racks. In two methods, feeder blocks pre-inoculated with laboratory-raised fungi were placed next to test specimens in an effort to accelerate decay. The treatments examined were CCA, copper chromate, alkaline copper high quat (AChQ), copper azole, azoles, kerosene, boron, TBTN, and copper naphthenate. Untreated *Corymbia maculata* heartwood was included for natural durability. Inspection was annual for four years.

The relative order of test site severity was Innisfail (most severe), Rotorua AFS, Rotorua, Clayton AFS and Clayton. The only H3 'natural' test methods (excludes AFS or pre-inoculated tests) where quarter-H3 CCA-treated *P. radiata* had reached less than 70% soundness were at Innisfail for the rot box after 2 years, the deck-on-grass and embedded tests after 3 years, and the ground proximity, painted embedded and double layer tests after 4 years. While the rot box was fastest, it gave an unusual relative order of failure. The most reliable tests that followed the average relative order of failure for all tests at all field sites were the deck-on-grass and ground proximity tests. The most reliable 'raised' test was the embedded test. Atypical results arose from tests pre-inoculated with laboratory fungi, especially at Rotorua where *Oligoporus placenta* was used. The in-ground stake tests, and trials in the AFS's at Clayton and Rotorua, also gave atypical relative orders of failure. Caution should be applied when using these artificial methods in H3 testing for registration purposes. Tests placed near-to-ground may be more reliable than 'raised' tests because they become inoculated by a wider range of fungal species from soil/leaf debris than in 'raised' tests where conditions are harsher and fewer species establish. Also, once those species establish in 'raised' tests they can then dominate the test and impose their own peculiar tolerances upon the results. This project has potentially reduced testing times from seven to three years at Innisfail. It is still beneficial to have more than one test type or test site. The most reliable and fastest tests are the deck-on-grass, ground proximity and embedded tests. The salient findings and methods discovered by this research will be submitted to the next update of the Australasian Wood Preservation Committee's 'Protocols for Assessment of Wood Preservatives'.

Introduction

The wood preservation and timber durability market is going through a period of rapid change, where new preservatives and protection systems need to be bought onto the market quickly. While laboratory tests and screening can be completed in a relatively short time (usually within six months), field tests are also needed to prove preservative efficacy because timber is often used in structural applications where reliable long-term performance is crucial. The designs for in-ground H4 testing are well established, involving stakes or posts partially buried vertically in the soil, or horizontally under the soil in fire prone areas (Lenz et al., 1992). A variation for H4 decay testing is the Accelerated Field Simulator (AFS), which is a humid heated room containing troughs of soil in which the stakes can be placed for exposure to a higher decay hazard (Cookson et al., 2000).

There is much greater variety in outdoor above-ground H3 decay testing (Fougerousse, 1976; De Groot, 1992), with three designs listed in the Australasian Wood Preservation Committee's (AWPC) protocols for preservative evaluation in Australia and New Zealand (decking, L-joint and flat panel tests) (AWPC, 2007). According to the AWPC, the H3 decay field test should include a reference preservative at its H3 approved, half and quarter retentions. Comparison with the candidate preservative can be made when the quarter retention of the H3 reference preservative, such as CCA, has significant biodeterioration (less than 70% mean soundness). To shorten field test durations, high hazard test sites are usually selected. In Australia, the highest hazard for above-ground decay occurs in the wet tropics of Queensland, where for example, Innisfail experiences an average rainfall of some 3.6 metres per year. Nevertheless, H3 decay trials are the slowest of the test procedures listed in the AWPC protocols, and even at Innisfail can take 6-7 years before the necessary level of decay will occur in the quarter retention of the reference preservative. Such a long testing duration can stifle innovation, and impedes commercial interest in the development of the H3 market.

One of the main issues to be aware of in H3 decay testing is the wide range of exposures that can occur within that hazard class. The extremes are probably best illustrated by considering window joinery and decking. Window joinery and mill work is usually painted and joints detailed to shed water, while decking is usually exposed and unpainted. The effect is highlighted with preservatives based on tributyl-tin (TBT), which have given good service life to window joinery, but concern when exposed in decking trials (Cookson and Hedley, 2005). TBT suffers degradation from ultraviolet radiation (Jermer et al., 1983; Archer and Meder, 1987), which can be alleviated to some extent by painting. This feature explains why at Hilo, painted TBTO-treated L-joints performed well, while similar unpainted timber did not (Archer et al., 1989).

Another difference is that basidiomycete fungi have greater relative importance in H3 than H4 exposure (Preston et al., 2000). H4 in-ground and cooling tower timbers are often significantly affected by soft rotting fungi as well. Many basidiomycetes respond well to laboratory culturing and cause rapid mass loss. Therefore, the soil-block decay test is useful for giving some information on the comparative performance of H3 preservatives, and can act as a screen to exclude some of the weaker preservative candidates from further testing. However, care is needed when interpreting laboratory decay tests and they are not a substitute for field testing. The soil-block test does not include natural weathering or UV exposure (so TBT performs well). Also, as pure mycelial cultures are mostly used, some fungi can decay treated timber more readily than when they are in a natural environment and in competition with other fungi. Therefore, copper-based preservatives often perform worse against copper-

tolerant fungi in laboratory bioassays than in the field, where inoculation may need to occur from spores that are more copper sensitive (Choi et al., 2002). Nevertheless, there is the potential to artificially accelerate decay in the field by including inoculation with laboratory grown basidiomycetes.

One example of the use of pure basidiomycete cultures in a 'field' trial is for the H1.2 hazard that occurs in New Zealand. This hazard is for interior wall framing that becomes excessively wet through rain penetration of the building envelope. The 'wall frame cavity test' simulates this exposure (Hedley et al., 2002). It involves a model stud wall built from test timbers, which is clad on either side to model an external wall. The unit is then inundated with water, and fungal inoculum placed inside the wall cavity. This is a relatively short term test, requiring a minimum of 12 months testing. While not a true H3 test, it shows that there may be some potential for the pre-inoculation of H3 field tests.

This research aims to develop and compare a range of H3 decay test methods likely to cause accelerated decay. The most likely way of accelerating decay is by maintaining dampness in test samples for longer periods. This may be achieved by increasing the proportion of water-trapping surfaces surrounding the test specimens. Another method for retaining moisture can be by painting and sealing several faces of the test specimens, although a problem here is that the choice of coating becomes a variable, and the effect of UV and weathering is reduced. Test units could be sprayed with water, although at some test sites this is impractical. 'Above-ground' test specimens in the AFS can be watered regularly, and could be placed outside over summer to obtain natural weathering (Cookson, 2010). As mentioned, acceleration could also be achieved by inoculating the test system with known wood decay fungi, rather than simply waiting for natural incursions.

This report describes the final, four year inspection of this accelerated H3 decay trial at five locations, Innisfail, Rotorua, Clayton, and AFS's at Clayton and Rotorua.

Methodology

Test sites

The test sites are:

1. Innisfail, at the Aeronautical and Maritime Research Laboratory, Palmerston Highway, Queensland. This is a wet tropical site.
2. Clayton near Melbourne, a cool temperate site.
3. Rotorua in New Zealand, a cool temperate site.
4. The AFS at Clayton, where incubation conditions are 28^{o}C and 85% relative humidity.
5. The AFS at Rotorua. This facility includes the 'termite house' where there is a constant temperature of 25^{o}C and 95% relative humidity. The termite house was used for the above ground exposures. There is also a region called the 'fungus cellar' where the temperature is 27^{o}C and relative humidity 85%. The fungus cellar was used for the in-ground stake trial at Rotorua.

Each year the exposures in both AFS's for the above-ground trials (not the in-ground stakes) will alternate between 9 months exposure inside the AFS, followed by 3 months field exposure during summer when test specimens will be subjected to natural weathering. In the first year however, timing was different as test specimens were ready for installation near the start of summer. If the pre-inoculated tests were placed directly outside during summer, the fungi may have died from desiccation. Therefore, AFS specimens were kept in the AFS for several weeks at Rotorua, and for 4.5 months at Clayton, before being placed outside on 5th December 2007 at Rotorua and 12th March 2008 at Clayton. These test specimens were returned to the AFS at Clayton on 3rd July 2008 and the AFS at Rotorua on 7th March 2008. Thereafter, the AFS exposed specimens at both sites were placed outdoors for the three months of summer, before being returned to the AFSs.

Test timbers and treatments

The main timber substrate used was *Pinus radiata*, obtained from Pine Solutions in Dandenong as MGP10 stock, 90 x 35 mm in 4.2 m lengths. It had a mean air dry density of 472 kg/m^3 (range 374-609 kg/m^3). The timber lengths were sorted and test specimens machined so that they contained sapwood only. Untreated *Corymbia maculata* heartwood was included in the trial, and was obtained from Burnetts Sawmill, Cran St, Bundaberg. It had a mean air dry density of 1080 kg/m^3 (range 930-1201 kg/m^3). Specimens with density less than 1000 kg/m3 tended to have paler colour to the higher density samples.

Pine clothes pegs, made in China, were bought from Bunnings Hardware in a pack of 150 pegs. The timber species was identified by Dr Jugo Ilic as being *Pinus massoniana* (Masson pine).

Test specimen dimensions varied according to the test exposure method employed:

- Flat panel test, 75 x 25 x 200 mm long (70 mm wide for *C. maculata*).
- Deck-on-grass, 75 x 25 x 300 mm long (70 mm wide for *C. maculata*).
- Raised deck placed approximately 1 metre above ground, 75 x 25 x 300 mm long (70 mm wide for *C. maculata*).
- Embedded test, 35 x 35 x 200 mm long.
- Embedded test, 35 x 35 x 200 mm long. Exposed surfaces painted.
- Embedded test pre-inoculated, 35 x 35 x 200 mm long.
- Rot box, 75 x 25 x 200 mm long (70 mm wide for *C. maculata*).
- Rot box pre-inoculated, 75 x 25 x 200 mm long (70 mm wide for *C. maculata*).
- Ground proximity test, 75 x 25 x 200 mm long (70 mm wide for *C. maculata*).
- Double layer test, 75 x 25 x 300 mm long (70 mm wide for *C. maculata*).
- In-ground stake test, 35 x 35 x 200 mm long.
- Peg test, pine clothes pegs, 72 mm long.

An overview of some of the trials installed is shown in Figures 1-2.

Figure 1. General view at Rotorua of double layer, decking and embedded tests upon installation.

Figure 2. General view at Rotorua of rot boxes, ground proximity (covered with black shade cloth) and flat panel tests (top right) on 5 December 2007, after rot boxes from the termite house were moved to the graveyard test area for summer exposure.

Moisture content

Three sets of untreated *P. radiata* test specimens were also exposed at Clayton, so that a set could be periodically removed and sectioned to determine their moisture content. There were 30 untreated specimens in the flat panel, embedded, rot box and ground proximity tests. Ten replicates from each test were removed during winter (9 months), a dry summer (15 months), and a wet summer (3.3 years).

To determine moisture content, each specimen was docked at their 50, 100 and 150 mm lengths to produce four quarters. Quarters were numbered consecutively from 1 to 4, where 1 was the metal tag end of the test specimen. Specimens were not removed from their frames unless they could be immediately docked and weighed to determine their initial wet masses. The quarters were then oven dried for two days, and their moisture contents determined. For the 3.3 year analysis, some of the quarters were also split in half, to give dorsal ('a') and ventral ('b') pieces, so that the moisture content of wood closest to the water-trapping regions of test frames could be determined. For the flat panel test, the bottom end (quarter no. 4) was split, to test the dorsal piece which rested against the water-trapping lip on the frame. In the ground proximity test, one of the inner quarters (no. 2) was split, so that the moisture content of the ventral piece resting directly on concrete block could be determined. A similar procedure was used for the rot box, although only those test specimens (one in each box) in the top layer was examined, as the other test specimens were fully enveloped by water-trapping surfaces. No additional sectioning was made to embedded test specimens, as the entire bottom quarter (no. 4) was already fully enveloped by water-trapping surfaces.

Test treatments

The majority of the trial examined an 'A' list of timbers and treatments, which were: Untreated heartwood of *C. maculata* (class 2 in-ground natural durability), water-treated *P. radiata* sapwood, and *P. radiata* sapwood treated with high flash kerosene (HFK) or one-quarter H3 retentions of CCA, AChQ (Alkaline copper high quat), azole LOSP and TBTN.

The 'B' list of treatments for exposure in the embedded tests at Innisfail and Rotorua only was: H3 retentions or potential H3 retentions of CCA, AChQ, Tanalith E, copper naphthenate (CuN), copper chromate (CC), boron (Solubor) and azole LOSP.

HFK was included as an example of a light oil treatment, and was obtained from Arch Wood Protection. The drum was labeled Mexcut H, and is a Shell product. It had a specific gravity of 0.80 at 15^{o}C, and a flash point at 78^{o}C. It contained 80% paraffins and napthenes, and 20% aromatics. A comparison of the specifications compared to AWPA P9 Type A is provided in Table 1.

Table 1: Comparison of AWPA P9 Type A oil and high flask kerosene (HFK).

Property	AWPA P9 Type A	HFK
50% volume distilling point (ASTM D-86)	254^{o}C min	245^{o}C min
90% volume distilling point (ASTM D-86)	307^{o}C min	360^{o}C min
Flash point (ASTM D-93)	>66^{o}C	>65^{o}C
Viscosity	3.46 cSt@38^{o}C min	3.524 cSt@40^{o}C min

The CCA used was Tanalith O (oxide), obtained from Arch Wood Protection. ICP analysis showed that it contained 9.2% Cu, 15.2% Cr and 12.4% As = 36.8% m/m TAE. For the quarter retention treatments, 32.27 g Tan O was made up to 20 L with tap water.

AChQ was obtained from Osmose, in two separate containers, i.e. 2 L of CAC (copper ammonium carbonate) and 1.5 L of DDAC (didecyl dimethyl ammonium chloride). The DDAC solution was analysed by Qld DPI&F and contained 40.5% m/m DDAC. To make 100 L of the one-quarter H3 treating solution, 360 ml CAC and 227 ml DDAC was made to 100 L. The elemental copper content of this treating solution was analysed and contained 0.31% m/m copper. The H3 treating solution was made by making 320 ml CAC and 200 ml DDAC up to 20 L. The DDAC concentration in the treating solution was much higher than anticipated, hence the higher quat loading and the reason for calling it AChQ rather than ACQ. Wood treated from several 'charges' or separate treating runs were chemically analysed (Table 2) to confirm that a mistake had been made in the quat retention. Although over-treated with DDAC, the AChQ-treated specimens were still acceptable for this project as the aim was to compare test methods rather than re-confirm ACQ performance.

The LOSP azole solution was Vacsol Azure provided by Arch Wood Protection. Chemical analysis showed that it contained 0.48% w/v tebuconazole, 0.47% w/v propiconazole and 0.33% w/v permethrin. That is, it contained 9.5 g/L total azoles.

TBTN was provided by Osmose. The product was Osmose Lifewood H3 (235WR), and contained TBTN (5%, or 1.2% m/v tin), permethrin (2%), white spirit (>90%) and dichlofluanid (5%). The solution provided for this project was 235WR, diluted by Osmose to contain 0.38% m/v tin. Therefore, the other ingredients were also diluted to the same extent. This diluted treatment solution provided by Osmose was used directly to treat the test specimens.

Concentrated Tanalith E was obtained from Arch Wood Protection, and contained 12.4% m/m copper and 0.49% m/m tebuconazole, so that total active ingredients were 12.89% m/m. The H3 treating solution was prepared by diluting 222.07 g Tan E concentrate to 20 L with tap water.

Copper naphthenate was supplied by Arch Wood Protection, and contained 5.5% m/m elemental copper, but no insecticide, resin or waxes. This CuN product met AWPA standards (synthetic naphthenics were absent). The H3 treating solution contained 2.182 kg of the concentrated CuN stock solution made up to 15 kg with white spirit.

Copper chromate (CC) was prepared by adding 77.5 g of $CuSO_4.5H_2O$ with 77.5 g $K_2Cr_2O_7$ and making the solution up to 20 L with tap water (therefore, 41.8% = Cu and 58.2% = Cr). Chemical analysis showed that the treating solution contained 0.098% m/m elemental copper. CC is not an approved treatment in Australia, although a recent review showed that there is sufficient efficacy data demonstrating its effectiveness, except perhaps for H3 exposure in softwoods (Cookson, 2001). CC was tested at similar total active elements to H3 CCA.

The boron treatment used Solubor (= Timbor), which is $Na_2B_8O_{13}.4H_2O$ and contains 21% elemental boron. The treatment solution was made by adding 208.375 g Solubor to 20 L water. Chemical analysis of the treatment solution showed that it contained 0.22% m/m boron. Boron is not approved for outdoor exposure. It was included in the trial to quantify its performance compared to 'non-leaching' preservatives. It was tested at the approved H2 retention.

Treatment schedules

The metal treatment tray used was 102 x 31 x 29 cm high. Test specimens had a moisture content of about 10.5% before treatment. Test specimens were weighed immediately before and after treatment to determine solution uptakes and retentions.

The LOSP treatment cycle for azoles, CuN and TBTN was mostly an initial vacuum of -55 kPa for 5 minutes, introduction of preservative while maintaining vacuum (usually taking 10 mins), release of vacuum and immediately open the cylinder door to drain the solution, and then apply a final vacuum of -90 kPa for 30 mins. Note that the test specimens were raised about 40 mm on a wire rack during the final vacuum, to keep them above any treatment solution removed during the final vacuum. The mean LOSP uptake was 60 kg/m^3 (75 L/m^3). A similar treatment cycle was used for HFK, except that the initial vacuum was -80 kPa for 5 minutes. The mean HFK uptake was 115 kg/m^3.

The water based preservatives and treatments (tap water, boron, CCA, AChQ, Tan E, CC) were applied using an initial vacuum of -95 kPa for 30 mins, one hour at 1400 kPa, and no final vacuum. Specimens were removed from the treatment solution and lightly surface

blotted before weighing. Specimens that floated were noted, and were generally excluded from the field exposure trials. Mean solution uptakes were 650 kg/m^3 (150-160% m/m).

Clothes pegs were treated by threading those required onto a length of wire, and placing them in the treatment tray with other test specimens. They were not weighed before or after treatment. A set of 10 pegs from each treatment has been kept in the laboratory, and could be used for chemical analysis if required.

Some 5110 timber *P. radiata* specimens were treated, from which the required 2300 *P. radiata* test specimens were selected. The water-borne preservative treated test specimens chosen for exposure had retentions mostly within 10% of the nominal retentions. Greater variety of uptake was obtained with the LOSP treatments (due to reduced solution uptakes rather than 'saturation' treatments), so that retentions mostly within 15-20% of the nominal retentions were accepted for exposure, although for HFK variation was up to 25% even though 2.2 times as many specimens were treated as needed (805 specimens treated from which 370 specimens were selected). There were ten replicate test specimens of each timber and treatment at each site and for each exposure method.

Chemical analyses of treated wood

Three or five spare treated specimens were selected for chemical analysis. The specimens selected were usually those with solution uptake retentions just higher than those used for the exposure trials, so were well treated. Retentions similar to each other were also selected, to reduce variability. The specimens for analysis were sent to Queensland DPI&F, who pooled the specimens belonging to each set, and conducted the analyses (Table 2). Additional AChQ treated specimens were sent to Osmose in Buffalo, USA for chemical analysis as well.

Numbering and painting

One set of embedded test specimens (35 x 35 x 200 mm long) were painted. On 15-16 September 2007, one end was masked temporarily with 47 mm wide packaging tape (end to be embedded). One coat of British paints 'All in One' sealer primer undercoat was applied, followed by two coats of Dulux Weathershield, vivid white low sheen acrylic.

After preservative treatment, air drying and painting, test specimens were numbered by imprinting the numbers onto stainless steel Dymo tape (without adhesive, 12 mm x 6.4 m rolls). These tags were nailed with brass boat nails near one end of each test specimen. In Australia, test specimens were generally positioned with the outer growth rings of the tree facing down and therefore exposed to any water entrapment provided by contact with timber in the test frames.

All treatments and test specimen preparation occurred at CSIRO.

Pre-inoculation

Pre-inoculated and colonized untreated *P. radiata* blocks were included in one aspect of the embedded and rot box tests. In Australia, half of the blocks were grown with the brown-rotting fungus *Gloeophyllum abietinum* (DFP 13851) and the other half with the white-rotting fungus *Perenniporia tephropora* (DFP 7904). In New Zealand, only brown-rotting fungi were

used, *G. abietinum* (a different isolate to the Australian *G. abietinum*) and *Oligoporus placenta*.

In Australia, fungi were grown in 12 stainless steel trays 370 x 225 x 95 mm high. A solution containing 1.2L of 2% agar and 1% malt extract was poured into each tray, covered with aluminium foil and autoclaved for 30 minutes. The trays were then placed in a sterile air bench to cool overnight. Each tray was inoculated with about 15 plugs of the appropriate fungus on 17 September 2007, and incubated at 25^{o}C.

Blocks for decay were 75 x 25 x 45 mm long and 35 x 35 x 45 mm long. Defects were allowed in these decay blocks. The blocks for decay, and plastic mesh, were sterilized by gamma irradiation.

After the fungi had grown sufficiently, a plastic mesh was placed upon the fungal mat. Sterilised blocks were placed end grain down upon the mesh and close packed within the trays on 24 September 2007. Pre-inoculated blocks were removed after five weeks (after four weeks for NZ grown fungi). *G. abietinum* showed good growth, with some mycelium on the top surfaces of blocks. Mycelium from *P. tephropora* was generally only 10 mm high on the sides of the blocks. For the Innisfail trials, pre-inoculated blocks were placed in two plastic bags according to fungal type and transported for installation with test specimens.

Bing^{TM} testing

Before installation, the Australian test specimens were packaged and sent to Queensland Department of Primary Industries and Fisheries (DPI&F) at Indooroopilly for sonic Bing^{TM} testing. The Australian test specimens were also Bing^{TM} tested after six months exposure (21-24 April 2008 at Clayton, 28 April-30 May 2008 at Innisfail), and after one, 1.5 and two years. Test specimens were Bing^{TM} tested just prior to them being probed with a knife for inspection. The results for this work are provided by Norton (2009).

Exposure methods

Flat panel test

Test panels were 75 x 25 x 200 mm (70 mm wide for *C. maculata*), and had a key hole cut before any treatment, which was an 8 mm diameter hole 40 mm from an end joined to a 4 mm wide slot 10 mm long.

Panels were hung from protruding flat head galvanized nails through the ‘key hole’, on a cross-batten (70 x 20 mm) of untreated spotted gum (*C. maculata*) or merbau (*Instia bijuga*) decking. Untreated ash eucalypt heartwood seasoned boards 65 x 19 mm were screwed to form an L-shape with similar timbers 31 x 31 mm, so that the bottom ends of panels rested in a trough (34 x 31 mm) upon the 31 x 31 mm timbers. In Australia, hardwood rather than pine was used to make the L-shaped troughs as while both timbers encourage brown and white rotting fungi (pine more so for brown rot) the hardwood lengths last longer on the frames. The frames were inclined at 45^{o} with the panels facing north for maximum UV exposure, although while exposed in the Clayton AFS the frames were laid flat. Panels were placed 10 mm apart within rows. At Innisfail, the timbers were attached to Dexion metal frames, while at the other locations they were attached to treated pine frames.

At Innisfail, test specimens were installed on 19 November 2007. Half (35) of the test specimens were placed on a relatively new frame installed six months earlier ('new frame'), while the other 35 panels were placed on a frame 4 y 9 months old ('old frame', Figure 3). There were five rows on each frame, and each row held one replicate of each A-list treatment, placed in random order.

Figure 3. Flat panel test installed at Innisfail on 'old frame'. The seven columns of test specimens on the right side of the frame are the test specimens for this project.

At Clayton (outdoors), test specimens were installed on 29 October 2007. The A-list panels were exposed on a ten year old frame (Figure 4). There were 14 specimens in each row, with two replicates of each treatment per row. A smaller new frame was made to accommodate the untreated *P. radiata* specimens that were to be used for moisture content determinations (Figure 5).

Figure 4. Flat panel test installed of A-list specimens at Clayton, on existing ten year old frame.

Figure 5. Flat panel test installed of water monitoring specimens at Clayton, on new frame.

At Rotorua, test specimens were installed on 16 November 2007 (Figure 6). Test specimens were attached through the keyhole with screws onto new H3 CCA-treated *P. radiata* 50 x 19 mm battens. The bottom ends of the test specimens rested on an L-shaped rebated rail of new untreated *P. radiata*, the rebate being approximately 50 x 20 mm. The samples were randomly arranged in two rows, with five samples from each treatment group in each row.

Figure 6. Flat panel test installed at Rotorua.

For Clayton AFS exposure there were four frames 600 mm wide and 740 mm deep. These could house seven panels in each row (Figure 7). For the A-list timbers in the AFS, one replicate was placed in each row. The tenth row of replicates was placed on the middle row of the fourth frame. The frames were installed in the AFS on 1 November 2007, and laid flat (Figure 8). They were placed outside on a concrete pad at Clayton on 12 March 2008, and bracing attached so that they were at 45^{o} and facing north. These test specimens were returned to the Clayton AFS on 3 July 2008, and laid flat.

Figure 7. One of the flat panel test frames installed at Clayton AFS.

Figure 8. Embedded test (foreground), rot box and flat panel test installed within steel troughs in the Clayton AFS.

Deck-on-grass

For the decking trials, each frame consisted of a middle bearer of 90 x 90 mm H4 CCA-treated *P. radiata*, and two side bearers 90 x 45 mm of H4 CCA-treated *P. radiata*. The bearers were kept in place with treated pine decking 70 x 20 mm nailed onto their ends. Test specimens rested upon a central 90 x 20 mm untreated *P. radiata* timber nailed onto the central bearer, and two 70 x 20 mm H3 ACQ-treated *P. radiata* timbers nailed onto the side bearers (Figure 9). The end grain of the test specimens abutted untreated 70 x 20 mm *P. radiata* nailed on edge. The test specimens were not pre-drilled for fixing. They were separated by about 5 mm with the aid of galvanised roofing nails (3-4 mm diameter), that should also prevent the test specimens from dislodging from frames during high winds. To allow test specimens to be removed for inspection, the two side pieces of untreated 70 x 20 mm *P. radiata* can be unscrewed from the side bearers, and test specimens slid from under the roofing nails.

Figure 9. Mock up of decking trials in Australia.

At Innisfail, test specimens were installed on sloping ground on 21 November 2007. There were two frames that each held two rows of test specimens (Figure 10). One longer row held 20 test specimens in random order (within sets of 7 timbers/treatments), and the shorter row held the remaining 15 test specimens.

Figure 10. Deck-on-grass, after three months at Innisfail.

At Rotorua, the decks on ground were installed 15 November 2007 on a relatively flat grassy area. Two 100 x 75 mm outer bearers and a central 100 x 100 mm bearer were placed on the ground, and spacers 100 x 50 mm nailed to each end. Boards 75 x 19 mm were nailed to the top of the bearers. On the outer 100 x 75 mm bearers these were H3, CCA-treated *P. radiata*. On the central 100 x 100 mm bearer they were untreated *P. radiata*, one either side of a 50 x 19 mm strip of untreated *P. radiata*, which was fixed on edge. A 70 x 20 mm H3 CCA-treated *P. radiata* batten was nailed along the outer side of the 100 x 75 mm bearers with the top edge at approximately the same height as the upper surface of the decking specimens.

The test specimens were installed in two rows with five samples from each treatment group randomly arranged in each row. The samples were loosely held in place on the central bearer with 75 mm long galvanised "springhead" (roofing) nails and on the outer bearer with 50 mm galvanised "hex headed" screws. The samples were 5-6 mm apart with the fastenings in the spaces between samples (Figure 11).

Figure 11. Deck-on-grass installed at Rotorua.

Raised deck

The frames for raised decks at the respective sites were constructed in the same manner as for the decks on ground.

At Innisfail, test specimens were installed on 21 November 2007. Two sets of decks (each with two rows) were placed on Dexion frames (Figure 12). Due to the slope at Innisfail, the ends of one frame were 94 and 117 cm above ground, while the ends of the second frame were 120 and 137 cm above ground.

Figure 12. Raised decking trial (on left), and embedded test (on right) after three months at Innisfail.

Frames at Rotorua were installed 15 November 2007, and the decks were approximately 1 m above the ground (Figure 13).

Figure 13. Raised deck installed at Rotorua.

Embedded test

The embedded test has similarities to the modified L-joint test described by Van Acker and Stevens (2003). A test specimen 35 x 35 x 200 mm long is embedded deeper than usual into untreated feeder boards of *P. radiata* (to encourage brown rot) and a non-durable hardwood such as *Eucalyptus regnans* (to encourage white rot), and to increase water trapping surfaces. The feeder boards were 90 x 35 timber lengths (stud size), with a deep rebate (60 x 18 or 19 mm) cut along one edge so that when bolted together they formed a deep U-shaped groove within which the test specimens were inserted (Figure 14). The galvanised bolts were 75 mm long and 6-8 mm in diameter, and five were needed when U-shaped holders were 2.4 m long. The bolt head was countersunk into the hardwood using a 25 mm diameter drill. These bolts can be loosened during inspections. Two untreated separators 35 x 35 x 45 mm long of *P. radiata* were inserted into the groove, one upon the other with grain horizontal, between each test specimen so that the bottom 60 mm or more of the test specimen was fully enclosed by untreated wood. In New Zealand these separators were single pieces 70 x 35 x 45 mm long.

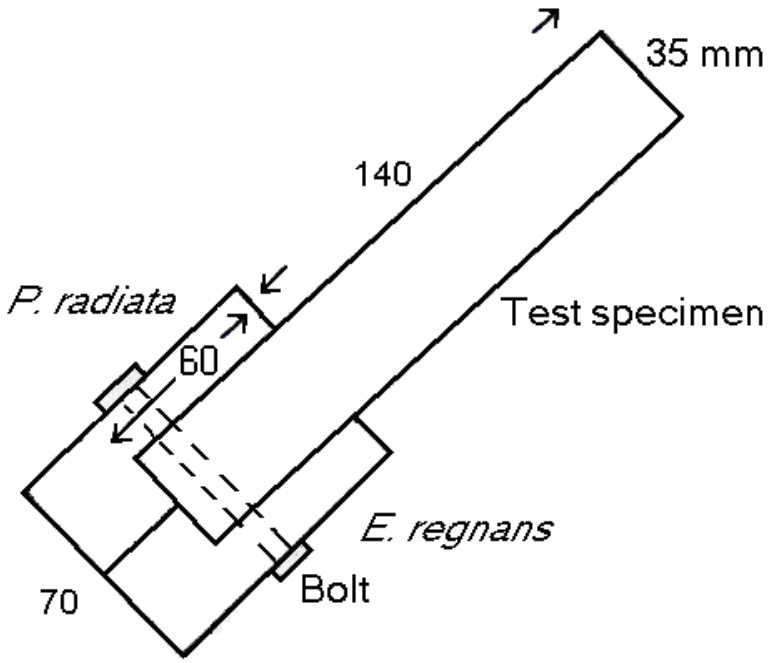

Figure 14. Profile of embedded test.

Two U-shaped holders rested within each V-shaped frame made from a 90 x 90 mm horizontal beam (100 x 100 mm at Rotorua) of H4 CCA-treated *P. radiata*. To support the U-shaped holders, two lengths of 300 mm wide fibre cement sheet 4.5 mm thick were nailed onto the beams using galvanised clouts. At Innisfail and Clayton, timber supports 70 x 19 x 250 mm long were nailed over the cement sheet at right angles to the beam, to support the weight of the cement sheet. The U-shaped holders rested at 45 degrees, so that rain would drain into the joint area. Because of the tilt, the hardwood piece was below the softwood. Alternatively, test specimens could be positioned vertically if the test area is limited, as

occurred in the AFS's at Clayton and Rotorua. The painted test specimens were inserted with the painted ends exposed, so the unpainted ends were hidden within the U-shaped holders.

At Innisfail, the frames were installed on 20 November 2007, and were 2.1 m long. They were fitted about one metre above ground on Dexion frames (Figure 15). The A-list, B-list and painted test specimens were randomised together within each frame.

Figure 15. Embedded test installed at Innisfail, painted specimens randomized with A- and B-list test specimens

At Clayton one frame was 2.4 m and the three other frames were 0.6 m long. They were placed directly on a concrete pad for exposure on 29 October 2007 (Figure 16).

Figure 16. Embedded test installed at Clayton., 2.4 m long

At Clayton AFS the holders were 0.6 m long, and were installed in the AFS on 1 November 2007. They were placed outside on a concrete pad at Clayton on 12 March 2008, but not in V-shaped holders. The test specimens were therefore orientated vertically. These test specimens were returned to the Clayton AFS on 3 July 2008.

It was found that the top edges of the U-shaped holders began to flair with weathering, so the enclosure of the test specimens was not as snug as sought. Therefore, after 3-4 months at Clayton, both the outdoor (19 March 2008) and AFS (12 March 2008) embedded test frames had their bolts moved halfway up the U-shaped holders (i.e., new holes were drilled through the bottom separators as well). At Innisfail, this change was made on 19 August 2008.

At Rotorua, the frames were installed in the field on 22 November 2007 and were mostly 2.4 m long. The V-shaped frames were checked into posts approximately 1 metre above the ground (Figure 1). A 15 mm thick batten was also fixed along the upper edges of the fibre cement on the inside of the "V", upon which the top ends of test specimens could rest. Plywood triangles 10 mm thick were nailed to the ends of the beams and the battens along the top edge of the fibre cement sheet. These have drain holes cut on two sides. The test specimens were exposed in U-shaped holders made from locally grown *E. regnans* and *P. radiata* sapwood. Half of the holders were set in the racks with the *P. radiata* strip upwards while the others have the *E. regnans* strip upwards. The U-shaped holders were placed under water spray for 1.5 hours prior to positioning on the exposure frames. The painted test specimens were placed in separate frames to the unpainted test specimens.

At Rotorua AFS, the U-shaped holders were 1.2 m long and were placed under water spray for 1.5 hours prior to positioning on the exposure frames in the termite house on 22 November 2007 (Figure 17). On 5 December 2007 the holders were removed from the termite house and installed in the graveyard racks for three months summer exposure. They were returned to the termite house on 7 March 2008.

Figure 17. Embedded tests on racks in Rotorua AFS.

Pre-inoculated embedded test

The separators placed between test specimens in the U-shaped holders for the pre-inoculated embedded test were two rows of 35 x 35 x 45 mm long untreated *P. radiata* at all sites. The bottom (deepest) row of separators was those that had been pre-inoculated. At Innisfail and Clayton AFS the fungi were *P. tephropora* and *G. abietinum*, while at Rotorua *P. tephropora* was replaced with *O. placenta*. These fungi were alternated within the holders, so that each test specimen was exposed to two different fungal species (Figure 18). Inoculated frames were installed separately to the uninoculated frames.

Figure 18. Pre-inoculated embedded test to be installed in the Clayton AFS. Top holder shows bottom layer of separators pre-inoculated with BR (brown rot) or WR (white rot). Lower holder shows the same specimens (photo cut and pasted), but with the top layer of uninoculated separators positioned.

At Innisfail, the frames were installed on 20 November 2007, and were 2.1 m long. They were fitted about one metre above ground on Dexion frames (Figure 19).

Figure 19. Pre-inoculated embedded test three months after installation at Innisfail, separate to uninoculated frames.

At Rotorua, the frames were installed in the field on 22 November 2007 and were mostly 2.4 m long. The U-shaped holders were placed under water spray for 1.5 hours prior to positioning on the exposure frames (Figure 20).

Figure 20. Rot boxes and embedded tests (pre-inoculated or not) at Rotorua under water spray for 1.5 hours prior to placement in the AFS or field.

The U-shaped holders for Clayton AFS were 0.6 m long, and were stacked in layers with test specimens vertical, within a stainless steel trough. They were not placed within V-shaped frames. When placed for outdoor summer exposure, the U-shaped holders were placed in the

same orientation directly upon the concrete pad. The specimens were placed in the AFS on 1 November 2007, outdoors on 12 March 2008, and returned to the AFS on 3 July 2008.

Figure 21. Pre-inoculated embedded test at Rotorua AFS when installed for summer exposure in graveyard on 5 December 2007. Note mycelium from the pre-inoculated blocks spreading up over the surface of the holders.

At Rotorua AFS, the U-shaped holders were 1.2 m long and were placed under water spray for 1.5 hours prior to positioning on the exposure frames in the termite house on 22 November 2007. On 5 December 2007 the holders were removed from the termite house and installed in the graveyard racks for three months summer exposure (Figure 21). They were returned to the termite house on 7 March 2008.

Rot box

The rot box was designed to both maximize water entrapment and to surround each test specimen with untreated wood that would encourage the establishment of decay fungi. Test specimens do not touch other test specimens directly, except perhaps at their corners. The sides of the open-topped box was made with by nailing two rough sawn H3 CCA-treated *P. radiata* (H4 CCA in NZ) 150 x 24 x 650 mm long to two pieces 445 mm long. The box needed to be large enough to accommodate swelling by the test specimens. In New Zealand, the internal dimensions of the boxes were 575 x 445 mm. Untreated merbau (kwila, *I. bijuga*) decking or H3 ACQ-treated *P. radiata* decking 70 x 20 mm was then nailed to the bottom, with 5-10 mm gaps between the decking to allow for drainage. Inside the box was lined with loose 20 mm thick untreated *P. radiata*, with pieces 140 mm wide on the sides and 70 mm wide on the floor (Figure 22).

Figure 22. Rot box lined with untreated *P. radiata*, prior to placement of test specimens.

The test specimens 75 x 25 x 200 mm long were installed with seven in each layer, in two rows, four in one row and three in the other. In each layer test specimens and untreated *P. radiata* feeder blocks of similar size were alternated so that test specimens were only in immediate contact with untreated *P. radiata* (Figure 23). The layout in the layers was also alternated so that test specimens were in contact with untreated *P. radiata* in the layers above and below. There was one test specimen from each A-list treatment group, randomised in each layer. Each box contained five layers, or 35 test specimens and 35 feeder blocks. There were two boxes at each site, and another two if pre-inoculated blocks were to be exposed as well. At Clayton, some of the untreated *P. radiata* feeder blocks were to be used for moisture content determinations.

Figure 23. Rot box installed at Clayton.

In Australia, some rot boxes became too tight when specimens swelled so that the top layer buckled slightly. Therefore, some of the side lining pieces of 20 mm thick untreated *P. radiata* were replaced with 15 or 10 mm thick untreated *P. radiata*. In future design, the boxes should be made a little larger again.

One end of each box (except during the AFS exposures) was raised slightly. As the top layer would receive the majority of UV exposure, and the lower layers should have greater moisture, the top layer will be rotated to the bottom after each annual inspection. The lower layers of timber became quite damp (perhaps excessively damp), so after the first year inspection, a sheet of nylon flywire was used to separate each layer slightly (a practice suggested by Prof. Holger Militz).

Rot boxes were installed on concrete pads at Clayton on 29 October 2007 (Figure 23), and Innisfail on 19 November 2007 (Figure 24). The Clayton AFS rot boxes were installed in the AFS on 1 November 2007 (Figure 25), outdoors on 12 March 2008, and back in the AFS on 3 July 2008.

Figure 24. Rot boxes installed at Innisfail. Left box is pre-inoculated.

Figure 25. Rot box installed at Clayton AFS, resting upon a flat panel frame. Showing bottom rows in trough upon which other tests will be stacked.

At Rotorua the ground was covered with plastic weed mat and 6 mm thick sheets of fibre cement. The boxes were placed on top of the fibre cement sheets on 5 December 2007 with a 45 mm thick bearer at one end to provide a slight slope, so that water could drain more readily out of the boxes (Figure 26). Rot boxes were installed in the Rotorua AFS termite house on 22 November 2007, placed outdoors on 5 December 2007, and returned to the termite house on 7 March 2008. At Rotorua, the rot boxes were watered for 1.5 hours prior to installation.

Figure 26. Rot boxes installed at Rotorua. The two boxes on the right were pre-inoculated.

Pre-inoculated rot boxes

In the pre-inoculated rot boxes the 75 x 25 mm untreated *P. radiata* separators between test specimens were only 110 mm long. A 75 x 25 mm block, 45 mm long was placed at either end of each separator. In Australia, the blocks were pre-inoculated with *P. tephropora* at one end and *G. abietinum* at the other. The arrangement of the two decay fungi blocks was alternated through each layer and between layers (Figures 27-28). In NZ, *O. placenta* replaced *P. tephropora.*

Figure 27. Bottom layer of test specimens and pre-inoculated blocks for Clayton AFS rot box. WR = white rot and BR = Brown rot.

Figure 28. Second bottom layer of test specimens and pre-inoculated blocks for the Clayton AFS rot box, alternating with the bottom layer. WR = white rot and BR = Brown rot.

Pre-inoculated rot boxes were installed on a concrete pad at Innisfail on 19 November 2007 (Figure 24). Pre-inoculated rot boxes were installed in the Clayton AFS on 1 November 2007 (in a separate trough to those not inoculated), outdoors on 12 March 2008, and back in the AFS on 3 July 2008. At Rotorua the ground was covered with plastic weed mat and 6 mm thick sheets of fibre cement were placed on top of that. The boxes were placed on top of the fibre cement sheets on 5 December 2007 with a 45 mm thick bearer at one end to provide a slight slope, so that water could drain out of the boxes. Rot boxes were installed in the Rotorua AFS termite house on 22 November 2007, placed outdoors on 5 December 2007 (Figure 29), and returned to the termite house on 7 March 2008. At Rotorua, the rot boxes were watered for 1.5 hours prior to installation.

Figure 29. Pre-inoculated rot box from the Rotorua AFS after moving to the graveyard for summer exposure. Mould patches and *O. placenta* mycelium have developed on untreated separators and some of the test specimens.

Ground proximity test

In Australia, the ground proximity test utilised Hebel blocks from CSR. These are light weight 600 x 200 x 100 mm thick blocks, and were coloured white. Twelve blocks at each site (Innisfail and Clayton) gave pads 1.2 x 1.2 m. At Innisfail, there were five rows each holding 13 test specimens, and a sixth bottom row holding five test specimens (total of 70 test specimens). At Clayton, the 70 A-list test specimens were interspersed with the 30 untreated *P. radiata* water monitoring test specimens (total of 100 test specimens). On the main 1.2 x 1.2 m pad, there were 15 test specimens per row. There was also a smaller pad 0.6 x 0.8 m at Clayton, needed to hold the additional specimens. These additional Hebel blocks were coloured pink.

The test specimens were placed upon the concrete block pads, and approximately 5-10 mm separated each test specimen. Shade cloth (70% UV shade rating) was then positioned over the exposure pad, and nailed to the top edge of a frame made from 150 x 25 mm H3 CCA-treated *P. radiata*. The shade cloth was therefore about 25 mm above the test specimens. The Clayton specimens were installed 29 October 2007 on flat ground (Figure 30), and the Innisfail test specimens were installed 22 November 2007 on sloping ground (Figure 31).

Figure 30. Ground proximity test installed at Clayton (shade cloth covers removed).

Figure 31. Ground proximity test after three months at Innisfail.

The ground proximity test at Rotorua was installed 15 November 2007 on a relatively flat grassy area adjacent to the flat panel rack. Plastic weed mat was placed over the ground (not done in Australia) and two layers of 40 mm thick pumice/cement slabs (390 x 190 mm) were placed on the mat. The samples were arranged in five rows of 14 samples, two samples from each treatment group randomly arranged in each row (Figure 32). There was a 5-10 mm wide gap between all samples. The test was covered by 70% plastic shade cloth on a 150 mm high, H3 CCA-treated *P. radiata* frame.

Figure 32. Ground proximity test at Rotorua, with shade-cloth frame removed.

Double layer test (modified)

In the double layer test all replicates of the same treatment are close stacked together, rather than being randomised with other treatments (Rapp and Augusta, 2004). The double layer test requires 11 specimens per treatment, with 6 on the bottom row and 5 staggered by half a width on the top row (Figure 33). In this trial, the eleventh specimen (lacking a metal number tag) was one of the rejected outliers in the batch used to obtain test specimens. The test specimen dimensions used here are different to what is recommended for the double layer test, to minimise the number of test block sizes in this comparative trial. Weed mat was placed on the ground under the frames to prevent grass growing through, which differs to the deck-on-grass trial. Bricks 100 mm thick were placed on the weed mat, onto which was laid a frame of three 90 x 90 mm H4 CCA-treated *P. radiata* bearers. H3 CCA-treated *P. radiata* 150 x 25 mm was nailed to the bearer ends to maintain their positions (Figure 34). Untreated *P. radiata* 70 x 20 mm were nailed on their edge to the CCA-treated bearers. The test specimens were placed directly on the CCA-treated bearers, with their end grain abutting the untreated pine. Each set of test specimens were separated using one untreated 75 x 25 x 300 mm *P. radiata* separators in the bottom row, and two as a continuation of the top row.

Figure 33. Mock up of double layer test, showing 11 specimens (10 test specimens, and one spare).

Figure 34. Double layer test after three months at Innisfail.

To accelerate decay, the test specimens were covered with shade cloth. The shade cloth frame was made of two sets of 150 x 25 mm H3 CCA-treated *P. radiata* (total height 300 mm). Shade cloth (70% UV shade rating) was nailed to its top edge. At Innisfail, this test was installed on 20 November 2007 (Figure 35).

Figure 35. Double layer test installed at Innisfail.

The double layer test was installed at Rotorua on 15 November 2007 (Figure 36). Two 100 x 75 mm outer bearers and a central 100 x 100 mm bearer of H4 CCA-treated *P. radiata* were placed on nine 90 mm thick concrete blocks on the weed mat. CCA-treated *P. radiata* spacers 100 x 75 mm were nailed between the bearers at each end and in the centre, in line with the supporting concrete blocks. Untreated *P. radiata* strips 75 x 20 mm were nailed to the bearers on edge, one in the centre of the 100 mm square bearer and one adjacent to the outside edge of each of the outer 100 x 75 mm bearers. A short 75 x 25 mm strip, on edge, was nailed across the ends of the longitudinal strips.

The test specimens were placed in two rows on the bearers, four treatment groups in each row, the eighth group being untreated *E. pilularis* heartwood from a 20-year old local plantation stand. The treatment groups were separated by a single untreated *P. radiata* sample in the bottom layer and by two similar samples in the top layer. At each end of each row there were one and a half untreated pine samples in the bottom layer, two in the upper layer. The whole assembly was covered by 70% plastic shade cloth fixed to a 300 mm deep H3 CCA-treated *P. radiata* frame around the outside of the test.

Figure 36. Double layer test installed at Rotorua (plastic strips nailed on bearers removed soon after installation, to be similar to the Innisfail frame).

In-ground stakes

Test stakes 35 x 35 x 200 mm long were inserted into the soil to a depth just covering their metal tags, so that about 40 mm of stake was above ground.

Stakes were installed in the Clayton AFS on 26 October 2007, all in the one soil trough (Figure 37). The soil was Toolangi forest loam, which has a high water holding capacity of about 65%. There were ten columns each containing seven stakes. One replicate of each A-list treatment was placed randomly within each column. The stakes were watered to maintain damp soil (about every two weeks).

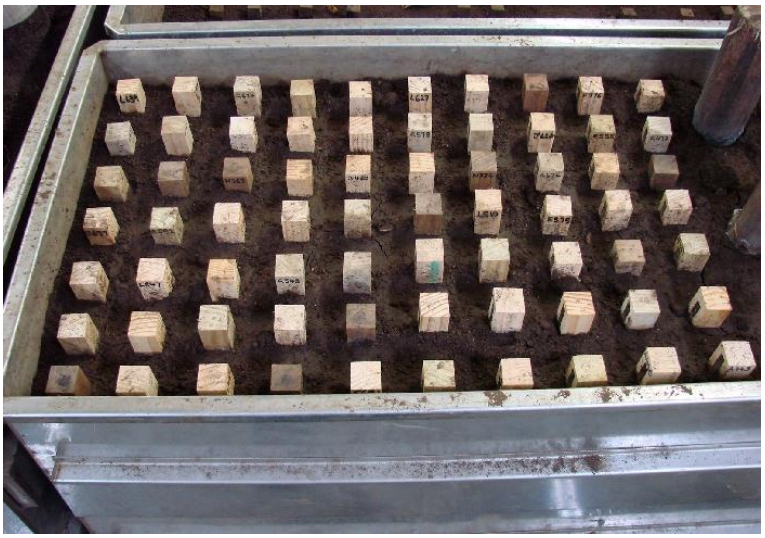

Figure 37. In-ground stakes installed in the Clayton AFS.

At Innisfail, the in-ground stakes were placed in a clearing within the rainforest exposure site on 22 November 2007 (Figure 38). They were placed in ten rows, with each row containing one replicate of the A-list treatments, in random order.

Figure 38. In-ground stakes in rainforest clearing at Innisfail, six months after installation.

Stakes were installed in the Rotorua AFS (southern chamber of the fungus cellar) on 23 November 2007, in seven plastic tanks (Figure 39). The temperature in this part of the AFS is 27°C and humidity is approximately 85%. The stakes were randomly arranged in the tanks, with at least one stake from each treatment group in each tank. The soil in the tanks was about 250 mm deep and was taken from old compost heaps adjacent to the nursery area at the Scion Rotorua campus. This soil contained a considerable amount of decayed wood debris from old seedlings and other plant material dumped from the nursery several years ago. The soil was lightly compacted around the stakes and the tanks were lightly watered after installation. The tanks and adjacent fungus cellar soil beds are watered lightly each week to keep the surface of the soil damp.

Figure 39. Stake test installed in Rotorua AFS (fungus cellar). Soon after this photo was taken, more soil was added and stakes pushed deeper, so they were the same depth as those in Australia.

Peg test

A test of treated pegs was included to see how small specimen size might affect time to failure. It was thought that the H3 result would contrast with in-ground H4 testing where thin stakes give faster results. Pegs could be inspected by simply squeezing them (pass or fail

strength test), and the effect of wood preservative on the metal hinge could also be noted. The pegs were not selected for sapwood, therefore some contained heartwood and defects such as small knots. If adopted, higher replicate numbers (e.g., 100) could be exposed than used in this preliminary trial, and the performance of preservatives in wood that includes defects could be readily obtained. The ten replicate pegs of each treatment were threaded together on a wire through their hinge. The pegs at Innisfail were installed 21 November 2007 (Figure 40), and those at Clayton on 29 October 2007 (Figure 41).

Figure 40. Clothes peg test after three months at Innisfail.

Figure 41. Clothes peg test installed at Clayton.

Inspection

The trial was inspected annually. The four year inspection at Rotorua occurred on 1-2 December 2011, Rotorua AFS on 2 December 2011, Clayton on 18 November 2011, Clayton AFS on 28 October 2010 and Innisfail on 3-5 November 2011.

Test specimens were removed from the exposure frames or soil and probed with a knife to determine the extent of decay (and termite attack for the in-ground stake trial at Innisfail). Specimens were given a performance rating of 8-0 (Thornton et al., 1991) based on the amount of cross-section lost (Tables 3-4). A rating of 8 means the test specimen is sound, while 0 is fully destroyed. A specimen rating 3 is considered to be unserviceable (it is not completely decayed or destroyed, and may have a central core of sound wood, but even so it would probably fail if flexed or trodden on). Test specimens were returned to the same position and orientation after each inspection. Table 19 gives an example of ratings for 75 x 25 mm specimen profiles in the flat panel test.

Table 3: Rating scale used to assess 75 x 25 mm test specimens.

Rating	Flat surface		Depth of end decay, mm. (add depths from both ends)	Description of decay
	Cross-section lost	Depth of decay or weathering from one (usually top) surface, mm		
8	No loss, sound	0	0	No decay
7	Up to 15%	0-3.75	0-5	Light decay
6	15–30%	3.75-7.5	5-10	Light-moderate decay
5	30–45%	7.5-11.25	10-15	Moderate decay
4	45–60%	11.25-15.0	15-20	Moderate-heavy decay
3	60–75%	15.0-18.75	20-25	Heavy decay
2	75–90%	18.75-22.5	25-30	Severe decay
1	90–99%	22.5-24.5	30-35	Severe-destroyed
0	100%	25.0	35+	Destroyed

The test specimen will be assigned the worst decay rating obtained from either the flat surface or end.

As an example in the flat panel test, the first signs of decay usually arise in the bottom edge of the panel that rests within the water trap rebate (lower flat face and end). In this edge, decay usually starts from the end grain rather than flat face, however, when the reverse happens and for ease of reporting, the greatest depth of decay from either the end or flat face is reported as lower end decay. Decay may also occur in the top end, and if this occurs, the depth is added to the lower end depth when deciding the panel's rating. The development of decay in several regions of the panel (e.g. top and bottom ends) shows that the treatment is failing rather than perhaps being influenced by an unnoticed defect at one end, which is why this information is retained by adding the two depths together to give a total end grain decay depth. The bottom end is considered to be like a joint, so rather than requiring 'destroyed' to be decay of the full 200 mm length of the test specimen, destruction is considered to have occurred when 35+ mm decay of the 'joint' has occurred. The 35 mm depth was chosen as representative of joint failure because in flat panel tests (test method long used at CSIRO), that is the depth

(approximately) of the trough of untreated ash eucalypt against which the bottom end of the test panels rest and where decay is most intense. Also, a depth of 35 mm allows 5 mm increments in an 8-point scoring system. It is also noteworthy that two ends of decking joined over a joist (or two joists joining over a bearer) would fail if both lost 35 mm from their ends. The top flat face can also suffer decay. When this 'decay' is just 1-2 mm deep, it can be difficult to distinguish macroscopically from surface weathering/defibration and for reporting purposes no distinction is attempted. The sides and flat underside are slow to decay, unless associated with end grain decay, so are not reported separately. The rating given according to the condition of the top flat face uses the system followed for in-ground stakes, according to percentage cross-section lost. The worst rating obtained from either region (top flat face, or ends) is the rating assigned to the panel.

Table 4: Rating scale used to assess 35 x 35 mm test specimens.

Rating	Flat surface or sides		Depth of end decay, mm. (add depths from both ends)	Description of decay (and termite attack for Innisfail in-ground stakes)
	Cross-section lost	Depth of decay or weathering from one (usually top) surface, mm		
8	No loss,	0	0	No decay
7	Up to 15%	0-5.25	0-5	Light decay
6	15–30%	5.25-10.5	5-10	Light-moderate decay
5	30–45%	10.5-15.75	10-15	Moderate decay
4	45–60%	15.75-21.0	15-20	Moderate-heavy decay
3	60–75%	21.0-26.25	20-25	Heavy decay
2	75–90%	26.25-31.5	25-30	Severe decay
1	90–99%	31.5-34.65	30-35	Severe-destroyed
0	100%	35.0	35+	Destroyed

Results and Discussion

This accelerated H3 decay trial was designed to compare 11 above-ground decay test methods (Table 5, not including in-ground stakes or 'B'-list). An in-ground stake trial was also included to allow comparison between H3 and H4 testing. The trial was installed in the field at Innisfail on 19-22 November 2007, Clayton on 26-29 October and Rotorua on 15-22 November. The trial was also installed in the Accelerated Field Simulators at Clayton on 1 November 2007, and Rotorua ('termite house' and 'fungus cellar') on 22-23 November 2007.

The main part of the trial examined an 'A' list of timbers/treatments: untreated heartwood of *Corymbia maculata* (class 2 in-ground natural durability), water-treated *Pinus radiata* sapwood, and *P. radiata* sapwood treated with high flash kerosene (HFK), or one-quarter (or potential one-quarter) H3 retentions of CCA, AChQ (alkaline copper high quat), azole LOSP and TBTN. The 'B' list of treatments was also installed in the embedded test only at Innisfail and Rotorua, and were H3 retentions (or potential H3 retentions) of CCA, AChQ, Tanalith E, copper naphthenate (CuN), copper chromate (CC), boron and azole LOSP.

A summary of the test methods and locations of installation are given in Table 5.

Table 5. Locations where each test method was installed.

Test method	Field test site			AFS	
	Innisfail	Rotorua	Clayton	Clayton	Rotorua
Flat panel	Yes	Y	Y	Y	
Deck-on-grass	Y	Y			
Raised deck	Y	Y			
Embedded test	Y	Y	Y	Y	Y
Embedded test painted	Y	Y		Y	
Embedded test inoculated	Y	Y		Y	Y
Rot box	Y	Y	Y	Y	Y
Rot box inoculated	Y	Y		Y	Y
Ground proximity	Y	Y	Y		
In-ground stakes	Y			Y	Y
Double layer test	Y	Y			
Peg test	Y		Y		
Embedded test, 'B' list treatments	Y	Y			

A set of untreated *P. radiata* test specimens were also exposed at Clayton, so that they could be removed and sectioned for the determination of moisture content and moisture gradients.

Chemical analysis

Chemical analysis by Qld DPI&F according to AS 1605-2000 of the treated test specimens showed that on average, the retention obtained was 9% less than expected from solution uptake, if the DDAC results are excluded (Table 6). Presumably, not all of the active ingredients can be removed from the wood during extraction for analysis, or there is some degradation and loss during the preparation stages for chemical analysis. The range was 32.9% less for H3 azoles, and a gain of 14.4% for copper in the high retention AChQ treatment. Treatments with closest match between solution uptake and chemical analysis were H3 CCA and copper chromate. The DDAC retention obtained from chemical analysis was approximately twice that expected from solution uptake, and is probably due to 'stripping', where DDAC is preferentially absorbed into wood out of solution (Tascioglu *et al*., 2005). Treating solution analyses are given in the Materials and Methods section.

Table 6. Retention of actives achieved in test specimens according to solution uptake and chemical analysis by Qld DPI&F, % m/m oven dried basis.

Treatment		Retention based on solution uptake, % m/m		Retention based on chemical analysis of treated wood, % m/m		
		Mean	Range	Mean	Range	% variance from soln uptake

Average, excluding DDAC results						-9.1

Moisture contents at Clayton

The moisture content (mc) of an additional set of untreated *P. radiata* specimens exposed at Clayton in the flat panel, rot box, embedded and ground proximity tests was determined during a winter (July 2008), a very hot summer (January 2009), and a mild wet summer (February 2011) (Table 7). In July 2008 there was 72 mm of rainfall and the mean maximum temperature was 13.3^{o}C. In January 2009 there was 0.8 mm of rainfall and the mean maximum temperature was 28.6^{o}C. In February 2011 there was 212 mm of rainfall and the

mean maximum temperature was 24.4^{o}C. The test specimens were docked into quarters and consecutively numbered with quarter no. 1 being the metal tag end.

In winter, the region of the flat panel adjacent to the water trap (quarter no. 4) had a slightly higher mc (33.6%) than the more exposed regions of the panel (22% mc). During the dry summer, the entire flat panel was uniformly dry with mean mc of 10.3%. During the wet summer, the region of the flat panel adjacent to the water trap had a slightly higher mc (17.0%) than the more exposed regions of the panel (12-15% mc). When this region (quarter no. 4) was examined in more detail by splitting in half, the ventral piece directly against the water trap had a mean mc of 19.4% (Table 8).

The water trap in the embedded test was more effective, as the embedded end of test specimens had a mean mc of 64.3% during winter. However, the specimens had dried out during the dry summer with mean mc of only 6.4%. This was the lowest mc in the tests, perhaps as frames rested directly on a concrete slab that may have been hotter (absorbed more heat) than frames on the ground (ground proximity) or raised (flat panel). During the wet summer, the bottom end of test specimens was 60.3% mc (Table 7).

As the ground proximity test specimens laid flat upon cement blocks, each quarter section had similar mc (although the top faces were observed to be drier than the face touching the cement blocks), with a mean of 69.1% during winter. Again, test specimens dried to a mean mc of 11.2% during the dry summer. During the wet summer the mean mc was 55.5% (Table 7), and when inner blocks were split in half the ventral portion had a mean mc of 70.6% (Table 8).

The wettest specimens were in the rot box, where the mean mc was 87.4% during winter, 69.0% during the dry summer and 119.3% during the wet summer (Table 7). When the layers in the rot boxes are considered separately, those specimens in the top exposed layer were driest (mean mc's 45.7% during winter, 10.6% during dry summer and 44.1% during wet summer). However at Clayton, the rot box design has kept test specimens too wet for significant decay to occur, with mean mc in the middle layer reaching 144% during the wet summer (Table 7).

Table 7. Moisture content of untreated *P. radiata* test specimens at Clayton after 9 months, 15 months and 3.3 years of exposure.

Test method	Position in specimen	9 months (July)	15 months (Jan) Hot dry summer	3.3 years (Feb) Mild wet summer
		Mean mc (sd)[1]		
Flat panel	1 (metal tag end)	22.2 (3.3)	10.5 (9.4)	12.3 (0.9)

Left, bottom layer of E specimens (ACQ) all rating 0, and A specimens (water) all rating 0 (spare blocks separating treatments removed for photo).

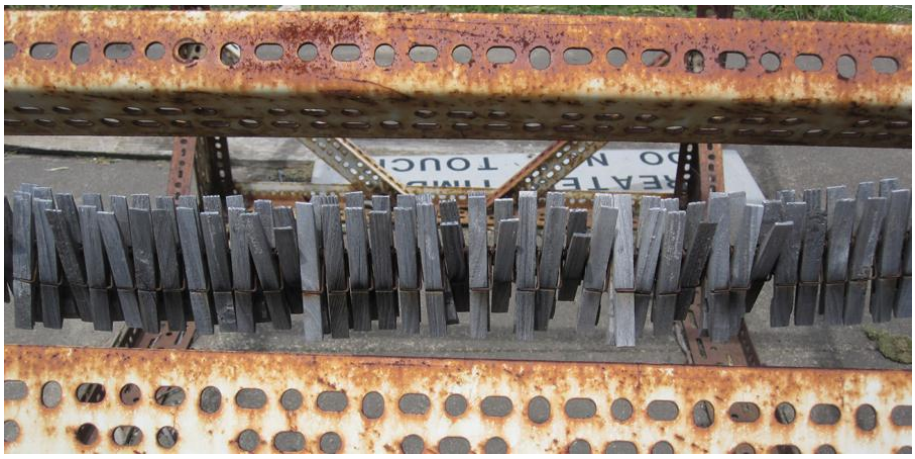

Figure 59. Peg test at Clayton after four years, no peg would break when opened.

Figure 60. Peg test at Innisfail after four years, some pegs broken or missing (except for their wire hinges).

Figure 61. In-ground stake in Clayton AFS after four years. Left to right = A451 water rating 0, L666 azoles rating 5, F847 TBTN rating 3, E582 ACQ rating 3, N370 *C. maculata* rating 7, G451 CCA rating 3, J514 HFK rating 0.

The mean ratings for the A-list treatments according to test method are given in Tables 9-15. Not all tests were installed at all sites (Table 5).

At Innisfail, water-treated *P. radiata* had failed (mean rating of 3 or less) in all tests except the peg test (Table 9, Figure 62). At Rotorua failure had occurred in the painted embedded test, ground proximity test, double layer test, and those tests pre-inoculated with *Gloeophyllum abietinum* and *Oligoporus placenta*, that is, the pre-inoculated embedded and rot box tests. Clayton was the least active of the field test sites, although water-treated *P. radiata* in the embedded test has now failed. Last year, Clayton field was the slowest site, whereas this year Clayton AFS was slower than Clayton field. In the Clayton AFS water-treated *P. radiata* had failed in the painted embedded, pre-inoculated (rot box and embedded) and stake tests. The Rotorua AFS was more active than the latter two sites, with failures of water-treated *P. radiata* occurring in all its tests, which were the pre-inoculated tests, as well as the embedded and rot box tests (not pre-inoculated) and the in-ground stake test.

Table 9: Mean ratings (sd) for water-treated *P. radiata* after four years (8=sound, 0=destroyed).

Test method	Field test site			AFS	
	Innisfail	Rotorua	Clayton	Clayton	Rotorua
Flat panel new frame*	0.0 (0.0)*	7.8 (0.4)		7.6 (0.7)	
Flat panel old frame*	0.0 (0.0)*		5.3 (2.8)		
Flat panel summary	0.0 (0.0)	7.8 (0.4)	5.3 (2.8)	7.6 (0.7)	
Deck-on-grass	0.0 (0.0)	5.8 (2.2)			
Raised deck	0.0 (0.0)	7.7 (0.7)			
Embedded test	0.4 (1.3)	4.1 (2.7)	1.7 (2.8)	3.1 (3.0)	0.2 (0.6)
Embedded test painted	0.3 (0.9)	1.7 (2.4)		1.6 (2.2)	
Embedded test inoculated	0.0 (0.0)	0.0 (0.0)		0.0 (0.0)	0.0 (0.0)
Rot box	0.0 (0.0)	4.9 (1.7)	7.2 (0.8)	7.5 (0.5)	2.3 (2.8)
Rot box inoculated	0.0 (0.0)	0.4 (1.3)		0.0 (0.0)	0.0 (0.0)

Double layer test	0.0 (0.0)	3.0 (2.5)			
Peg test	4.0 (2.2)		8.0 (0.0)		
In-ground stakes	0.0 (0.0)			0.9 (1.3)	0.0 (0.0)

*Five replicates

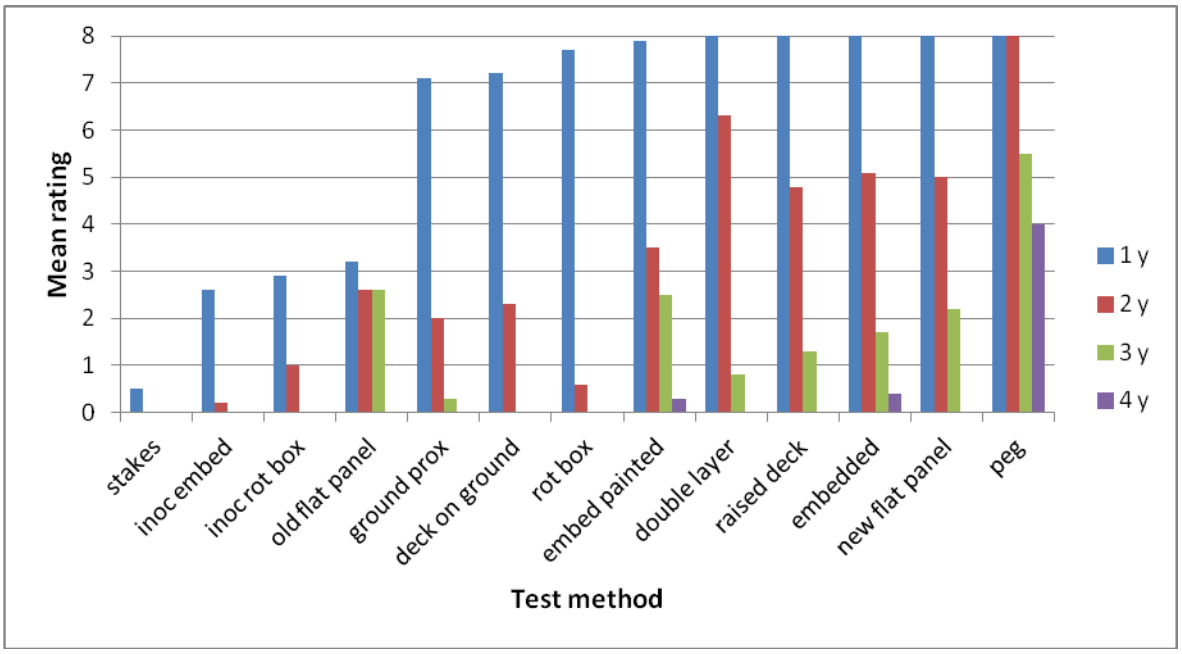

Figure 62. Relative performance of water-treated *P. radiata* at Innisfail after one to four years.

Of the in-ground stake trials, Innisfail was most active against water-treated *P. radiata*, with damage being caused mainly being white rot, although some stakes were damaged by termites as well. The Clayton AFS stake test was slower, with a mean rating of 0.9. The Rotorua AFS stake test was in a more active 'forest nursery compost' and the mean rating was 0.0 for water-treated *P. radiata*.

The most striking change after the first year inspection was the sudden failure in the rot boxes (not inoculated) at Innisfail at the two year inspection, and the rating there for water-treated *P. radiata* is now 0.0. At Innisfail during the two year inspection, a previously used 'old' flat panel test frame behaved like a pre-inoculated test, as a brown rotting fungus (*Fomitopsis lilacinogilva*) caused extensive decay with a mean rating of 2.6 (5 replicates), while on the newer frame the mean rating was 5.0. After four years the ratings were 0.0 on both frames for water-treated *P. radiata* (Table 9).

HFK was the next most susceptible treatment (Table 10, Figure 63), and generally followed the pattern of decay found for water treatment. For example, HFK-treated *P. radiata* in the embedded test at Clayton had a mean rating of 2.2 compared to 3.1 for water-treated *P. radiata*. Exceptions appear to be where solvent evaporation would have been inhibited, which was shown in the earlier rather than later inspections. For example after two years, the pre-inoculated rot box at Clayton AFS caused only moderate decay (mean rating 5.8) to HFK-treated *P. radiata* compared to a mean rating of 0.0 for the water treatment. Being surrounded by soil also appeared to reduce solvent evaporation, as after one year at Innisfail the mean ratings for stakes treated with HFK or water were 4.6 and 0.5 respectively.

Table 10: Mean ratings (sd) for HFK-treated *P. radiata* (8=sound, 0=destroyed) after four years.

Test method	Field test site			AFS	
	Innisfail	Rotorua	Clayton	Clayton	Rotorua

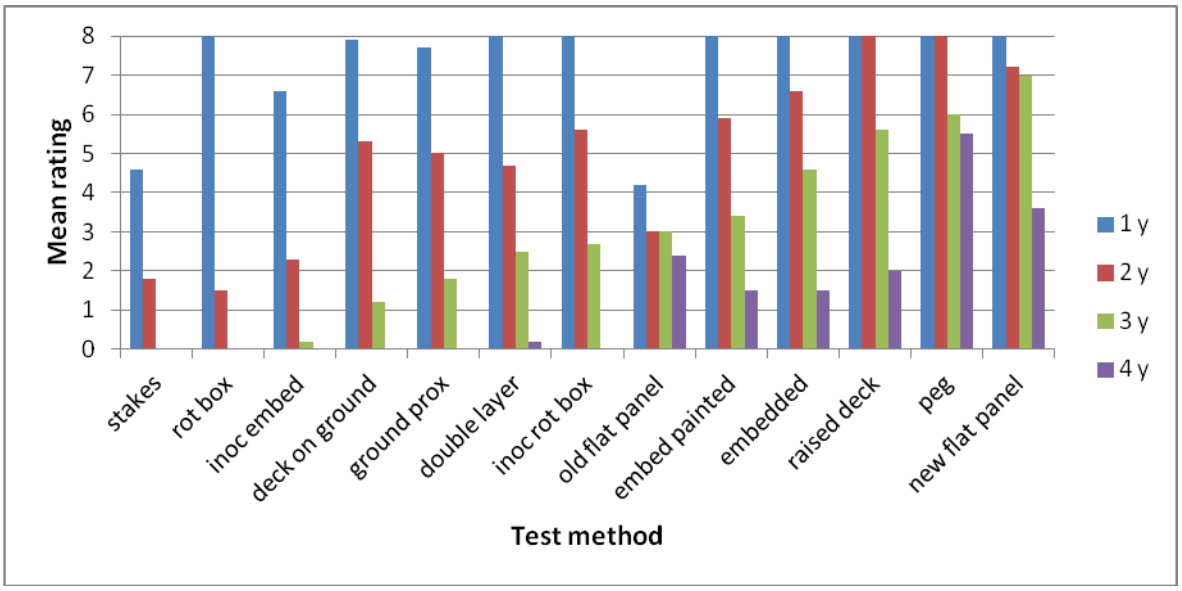

Figure 63. Relative performance of HFK-treated *P. radiata* at Innisfail after one to four years.

At Innisfail after four years, quarter-H3 AChQ-treated *P. radiata* (Table 11, Figure 64) had failed (mean rating 3.0 or less) in the deck-on-grass, ground proximity, double layer and in-ground stake tests. No treatment failures in the field had occurred at Rotorua or Clayton. However, the treatment had failed in the AFS's at Clayton and Rotorua in the embedded tests and in-ground stake tests. Oddly, there was a sudden failure of this treatment in the double layer test at Innisfail when the mean rating fell from 6.0 (2 years) to 0.7 after three years (Figure 64). It is surprising that AChQ did not perform even better given the very high quat retention used in this trial, suggesting there is a limit to how much additional quat is useful to the ACQ formulation.

Table 11: Mean ratings (sd) for quarter-H3 AChQ-treated *P. radiata* (8=sound) after four years.

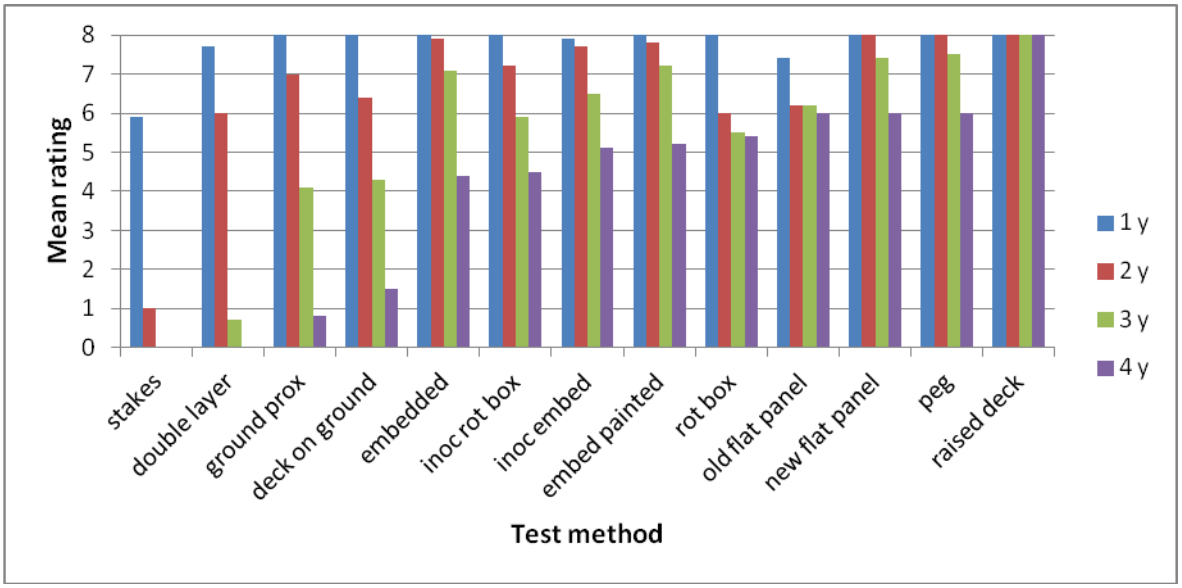

Figure 64. Relative performance of AChQ-treated *P. radiata* at Innisfail after one to four years.

CCA is the most common reference preservative used in above ground decay trials. The most severe above ground trial was the rot box (uninoculated) at Innisfail, with heavy decay after two years (mean rating of 3.8) and three years (mean rating 2.3) although little changed after four years (mean rating 2.1) for *P. radiata* treated to quarter-H3 CCA retention (Table 12, Figure 65). These test specimens were still sound after one year, showing that once significant decay started in the rot box it progressed rapidly through many of the treatments. Interestingly, quarter-H3 CCA treated *P. radiata* in the pre-inoculated rot boxes had a mean rating of 6.9 after three years, suggesting that the fungi selected had inhibited colonization by

the more aggressive local species. Decay was very limited or absent from similar test specimens in the other rot boxes (uninoculated) at the other four sites.

Useful results from field tests usually occur when the quarter-H3 CCA retention has reached a mean rating of 6.0 or lower. Field tests achieving this threshold after three years at Innisfail were the rot box, deck-on-ground, embedded test, double layer test and pre-inoculated embedded test. After four years at Innisfail additional tests reaching this mark were the painted embedded, the pre-inoculated rot box, and ground proximity tests. At the other sites a mean rating of 6.0 or less was achieved for the pre-inoculated embedded test at Rotorua (2 years), the same test at Rotorua AFS (4 years) along with the embedded test (3 years) and pre-inoculated rot box (4 years), and the painted embedded test at Clayton AFS (4 years). The quarter-H3 CCA treated *P. radiata* in-ground stakes also had significant decay, with mean ratings of 0.3, 0.9 and 2.4 for stakes placed at Innisfail, Rotorua AFS and Clayton AFS respectively.

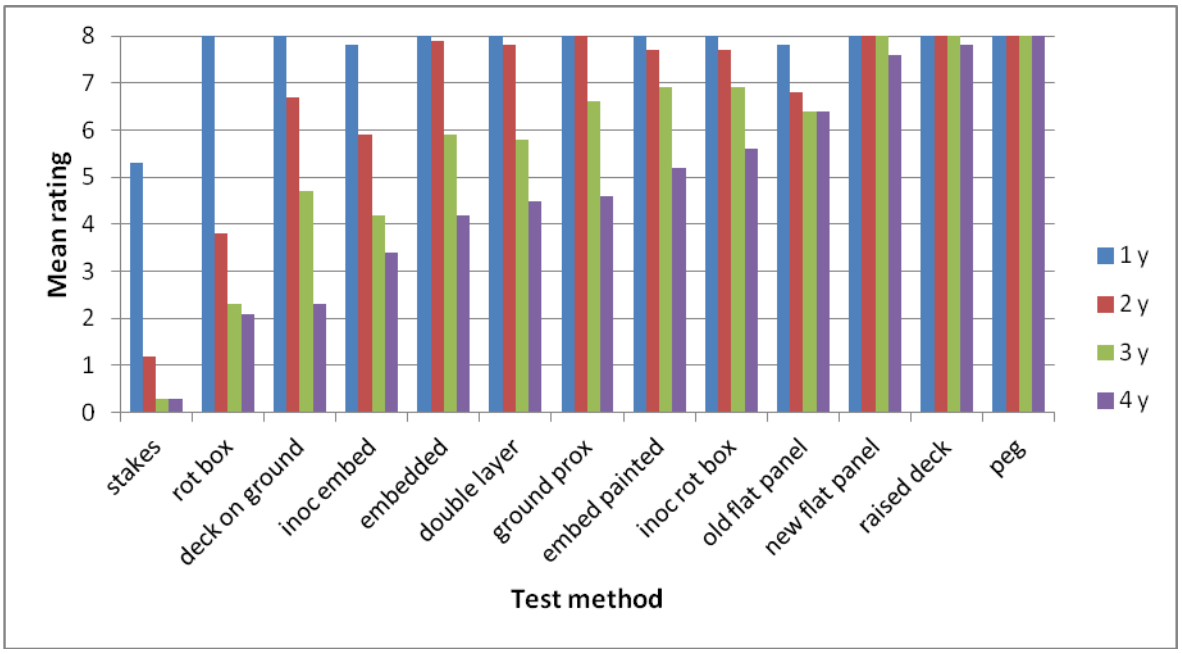

Figure 65. Relative performance of quarter CCA-treated *P. radiata* at Innisfail after one to four years.

After two years, the quarter-H3 LOSP azole-treated *P. radiata* test specimens had only moderate to no decay in the various above ground trials, except in New Zealand where rot boxes and embedded tests pre-inoculated with *O. placenta* had heavy decay. After three years at Innisfail, there was also moderate-heavy decay in the raised deck (mean rating 4.1) and double layer (mean rating 4.2) tests (Table 13, Figure 66). Decay in the raised deck was clearly due to one particular species of brown rotting fungi, later identified as a species of *Heterotextus* (Figure 67).

Table 13: Mean ratings (sd) for quarter-H3 azole-treated *P. radiata* after four years (8=sound).

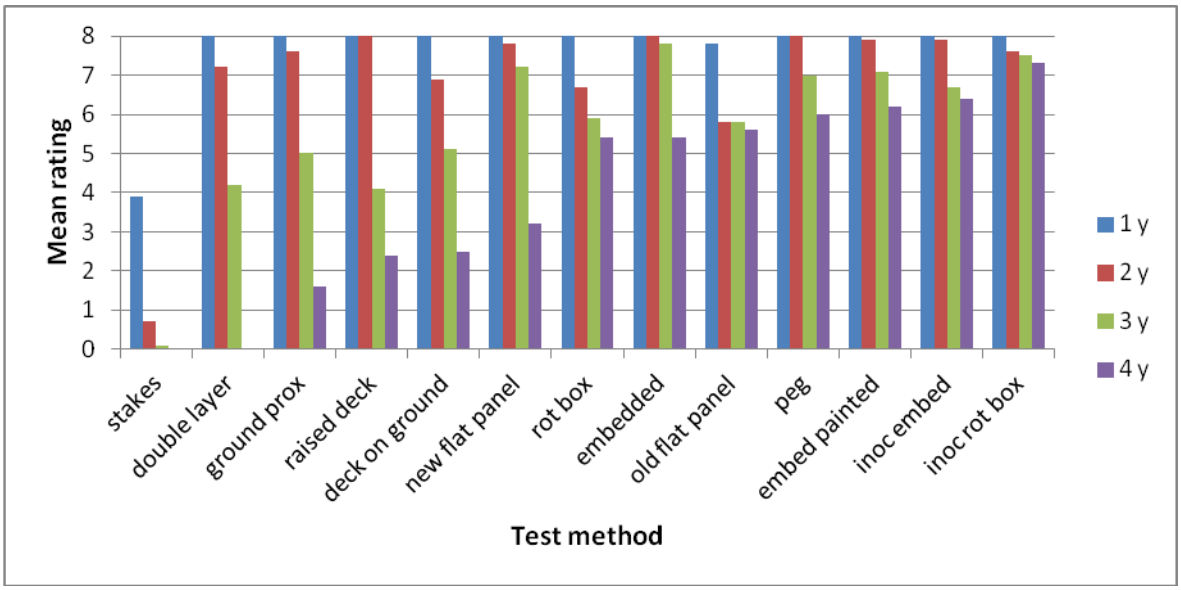

Figure 66. Relative performance of azole-treated *P. radiata* at Innisfail after one to four years.

Figure 67. Fruiting bodies of the brown rotting fungus (*Heterotextus* sp.) responsible for extensive decay in quarter azole-treated *P. radiata* test specimens in the raised deck test at Innisfail after three years.

At Innisfail, the quarter-H3 TBTN-treated *P. radiata* test specimens had failed (mean ratings below 3.0) in the deck-on-ground, embedded tests painted or pre-inoculated, ground proximity and double layer tests (Table 14, Figure 68). It should be noted that the TBTN formulation included dichlofluanid, with unknown influence on efficacy. The in-ground stakes had mean ratings of 0.0, 0.3 and 2.8 at Innisfail, Rotorua AFS and Clayton AFS, respectively (Table 14). A coating of paint has been shown previously to improve the performance of TBTN; however, no such improvement occurred in the current trial with embedded tests. Perhaps too large a surface area was left uncoated, as the bottom end and sides of painted embedded test specimens were not coated with paint. However, these surfaces were then embedded within the test frame so were not exposed directly to the sunlight.

Table 14: Mean ratings (sd) for quarter-H3 TBTN-treated *P. radiata* (8=sound) after four years.

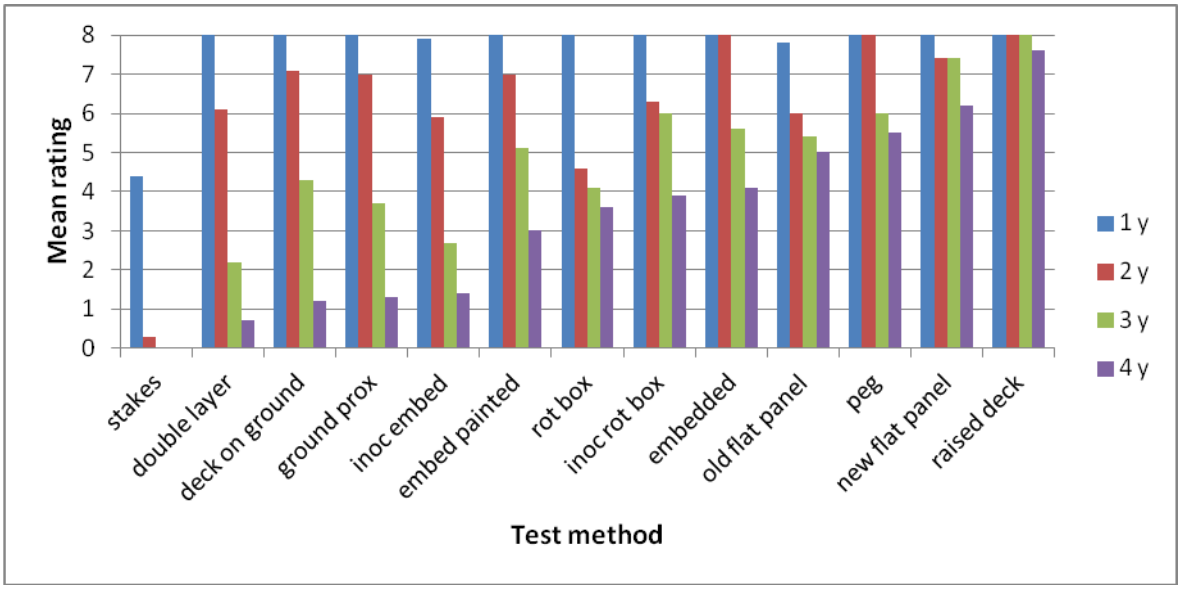

Figure 68. Relative performance of TBTN-treated *P. radiata* at Innisfail after one to four years.

The naturally durable heartwood of *C. maculata* had some decay, mainly white rot, in some tests. However, mean ratings were above 7.0 in all above ground tests at all sites, except the painted embedded and ground proximity tests at Innisfail (Table 15, Figure 69). It was also the best performing timber in the in-ground stake trial at Innisfail, with a mean rating of 6.7.

Table 15: Mean ratings (sd) for untreated *C. maculata* heartwood after four years (8=sound).

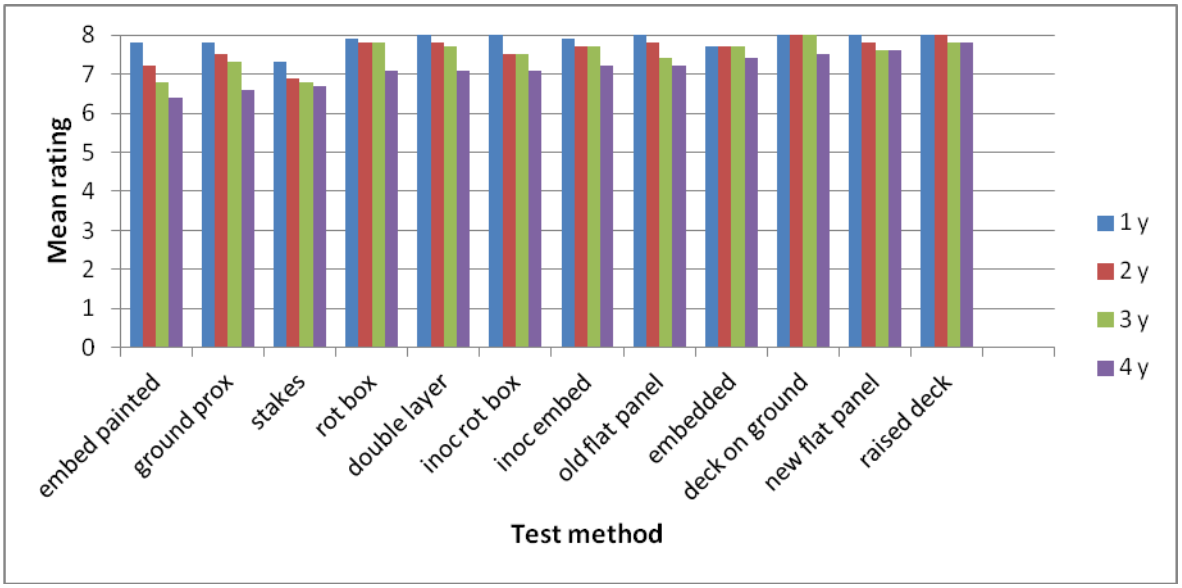

Figure 69. Relative performance of untreated *C. maculata* at Innisfail after one to four years.

The embedded tests of the 'B-list' treatments at Innisfail and Rotorua were mostly in good condition with only light or no decay (Table 16). The exception was the boron treatment with a mean rating of 0.6 at Innisfail and 5.1 at Rotorua. Copper naphthenate was also starting to separate as a less effective preservative from the other 'H3' preservatives of copper chromate (not currently approved in Australia/NZ), Tanalith E, AChQ, azoles and CCA.

Table 16: Embedded test, A and B list timber/treatments after four years, mean ratings (sd).

Treatment	Innisfail	Rotorua	Mean both sites
Water	0.4 (1.3)	4.1 (2.7)	2.3
HFK	1.5 (2.0)	3.9 (2.5)	2.7
Boron	0.6 (1.3)	5.1 (2.9)	2.9
TBTN quarter-H3	4.1 (3.3)	6.6 (1.3)	5.4
AChQ quarter-H3	4.4 (3.6)	6.9 (1.0)	5.7
CCA quarter-H3	4.2 (3.6)	7.8 (0.4)	6.0
Azoles quarter-H3	5.4 (2.4)	7.6 (0.7)	6.5
Copper naphthenate H3	6.3 (2.5)	7.4 (0.8)	6.9
Spotted gum heartwood	7.4 (1.0)	7.6 (0.5)	7.5
Copper chromate H3	7.4 (1.1)	7.6 (0.5)	7.5
Tanalith E H3	7.5 (0.5)	7.6 (0.5)	7.6
AChQ H3	7.7 (0.5)	7.8 (0.4)	7.8
Azole 'H3' (0.041% m/m)	7.8 (0.6)	7.8 (0.4)	7.8
CCA H3	7.6 (0.8)	8.0 (0.0)	7.8

Bing testing

Bing^{TM} testing is an acoustic method for evaluating the mechanical properties of wooden test specimens. It can measure the modulus of elasticity (MOE) in compression and flexure. During the first two years of this trial, researchers at the Queensland DPI&F Bing tested all of the Australian exposed test specimens every six months. Their 12 and 24 month testing could also be compared with the 'pick' test results obtained by probing with a knife. The full report on Bing testing was provided by Norton (2010). Some findings were that MOE in compression gave variable results and was not suitable for detecting decay or insipient decay reliably. However, MOE in flexure gave useful results. It predicted that the deck-on-grass, inoculated rot box and rot box at Innisfail had significant MOE^f differences after 12 months compared to when first installed. Pick testing confirmed that these were amongst the fastest tests at Innisfail. Also, the least aggressive test was predicted to be the flat panel test, and this was confirmed to be amongst the slowest tests at Innisfail along with the raised deck and peg tests after 4 years (peg test not Bing tested). The Bing test also predicted that TBTN was the worst of the quarter-H3 treatments being examined (apart from water and HFK), which was confirmed in later inspections. Bing testing therefore appears to offer a method for detecting and making decisions about decay earlier than could be made by pick testing.

Test site comparisons

Innisfail was clearly the fastest test site, while Rotorua was only slightly faster than Clayton (Table 17). This trend follows their mean annual rainfalls of 3600 mm, 1400 mm and 700 mm

respectively. It should be noted however that there were slight differences between sites in all but the ground proximity tests. Half of the flat panel test at Innisfail was on an old frame, all of the test at Clayton was on an old frame, while at Rotorua it was on a new frame. Also, the embedded tests at Innisfail and Rotorua were raised, while at Clayton they were on a concrete pad. The rot boxes at Innisfail and Clayton were on concrete pads while at Rotorua they were on weed mat on the grass. Results now suggest that such differences can have an important effect on decay rates. The ground proximity tests at each site were placed on grass and all were on new or uncontaminated masonry blocks/pavers. The ground proximity test suggests that Rotorua is a faster decay site than Clayton.

If including a comparison of the AFS's, the Clayton AFS was the slowest AFS for the embedded and rot box tests (average of 7.7) compared to Rotorua AFS (average of 4.9) and the field sites. Clayton also had the slowest stake test. The Rotorua AFS was nearly as fast as the Innisfail test site for the embedded and rot box tests.

Table 17: For those tests common to each site, average of mean ratings for the seven treatment/timber variations in each test at each site after four years.

Test	Field test site			AFS	
	Innisfail	Rotorua	Clayton	Clayton	Rotorua
Flat panel	4.8	7.6	7.4	8.0	
Embedded	3.9	6.4	5.4	7.4	3.8
Rot box	3.4	7.0	7.9	8.0	5.9
Ground proximity	2.1	5.8	7.1		
Average of means	3.6	6.7	7.0		
Average of embedded and rot box tests	3.7	6.7	6.7	7.7	4.9
Stakes	1.0			3.2	1.4

Fast and reliable tests

Method of comparison

The main aim of this project was to find the fastest H3 test method that would also give reliable results with broadest application. The fastest test would be judged according to how quickly the quarter-H3 CCA-treated pine reached a mean rating of 6.0 or less, a time according to the AWPC protocols when there is sufficient decay for candidate preservatives to be compared. Other 'reference' preservatives could have been used, however CCA is the most widely used and understood preservative. The other requirement was that the test should give a representative relative order of failure to the seven treatment/timber variations examined. The seven treatments/timbers used included the main preservative types currently in use, as well as a non-durable timber (water-treated *P. radiata*), a low retention 'oil' preservative (HFK) and a naturally durable heartwood (untreated *C. maculata*). The relative order of failure of these main treatments/timbers was determined by averaging the mean ratings for all H3 field tests at each site after three years (Table 18) and four years (Table 19). The three year results (Table 18) were included in the consideration as a check on consistency in the relative order of failure. Excluded from this determination of relative order were the in-ground stake tests, those tests that had been pre-inoculated, and those tests conducted in an AFS. Only H3 tests naturally infected with fungi and always field exposed were included at this stage.

Table 18: Relative order of failure determined from mean ratings at the three year inspection for all field test sites.

Test site	Test	Water	HFK	TBTN quarter	AChQ quarter	Azole quarter	CCA quarter	Spotted gum
Innisfail	Flat panel	2.4	5.0	6.4	6.8	6.5	7.2	7.5

The relative order of failure was the same after three and four years, and the mean for both is also given in Table 19. The mean rating for ACQ quarter H3 and azoles quarter H3 were virtually identical at 6.4 and 6.5 respectively, so these treatments are considered equivalent in the ordering. The next step was to list the individual tests and sites according to their ability to match this mean relative order of failure (Table 20).

Table 20 compares the ability of each test to meet the average relative order of failure for the whole test, or the extent to which they differed. Tests were broken into groups, such as those that met the order exactly (results # 1-7), or were out by one preservative (results 16-28) or two (results 40-43). For example, the ground proximity test at Rotorua (result 4) met the relative order of failure exactly, so is a reliable test although too slow as the quarter-H3 CCA-treated *P. radiata* was still rating 7.6 after four years. Note also that the relative order of failure was considered correct if several means were the same, such as the peg test at Innisfail where there were two means at 5.5 and two at 6.0 (result 2). Similarly, some tests had several means of 8.0 (e.g. results 5-6) so had not failed to meet the correct order at this stage. However, the reliability suggested for these tests should be viewed with caution, as it is quite likely that when mean ratings differentiate in future inspections the tests would be shown to

be less reliable. No conclusion could be drawn for the peg test at Clayton (result 46) as all means were 8.0.

Table 20: Comparison of tests according to their ability to meet the relative order of failure found for all field tests.

Some tests had several 0.0 ratings, so were fast tests. Again, these tests were not penalized for spanning the correct order with the same score, as shown for the Innisfail stake test (result 3) where there were five 0.0 ratings out of a possible seven. However, for test results where there were two or more 0.0 ratings, earlier inspections were examined until a clear relative order of failure could be found (from the 1, 2 or 3 year inspections). So for the Innisfail stake test only the first year inspection lacked two or more 0.0 ratings (result 44), and this result revealed that in-ground stake tests at Innisfail were quite unreliable for predicting the relative order of failure in above-ground tests. Other tests where this process was used were results 1, 9, 20, 22, 30, 43, and the inspection year used is included with their entry in Table 20.

A further variation was to determine which tests varied only slightly from the exact order required. Some tests would meet the order if an arbitrary rule was applied where one change in rating by + or - 0.5 of a rating point then bought the test into the desired relative order. For example, results 8-15 were bought into order by adding or subtracting 0.5 from (only) one of their mean ratings. The embedded painted test at Rotorua (result 11) met the desired order, except that the mean rating of 7.1 for untreated *C. maculata* was lower than for CCA-treated *P. radiata* at 7.3. By adding 0.5 to 7.1 (or subtracting up to 0.5 from 7.3) the required relative order was achieved.

A similar process was used to find those tests that differed from the desired order by only one rating after the ± 0.5 rule was applied (results 29-39), or by 2 ratings after the ± 0.5 rule was applied (results 44,45). For example, the raised deck at Innisfail (result 31) has a mean rating for azoles much lower than expected, and also the rating for ACQ (rating 8.0) is a little higher than for both CCA and untreated *C. maculata*. By subtracting up to 0.5 from 8.0, the order is restored except for the azole result. Similarly, the in-ground stakes after 1 year at Innisfail (result 44) could have 0.5 subtracted from the HFK rating of 4.6 to make it lower than for TBTN. But then, two other scores are still out (TBTN at 4.4 higher than azole at 3.9, and ACQ at 5.9 higher than CCA at 5.3).

Reliability comparisons

From Table 20 some interesting trends appear. Some results can mostly be ignored because the tests have been too slow so there are many 8.0 scores (e.g. results 5-7 and 13-15) or too fast so there are too many 0.0 scores (e.g. result 3). Otherwise, the most reliable tests were the ground proximity tests at Rotorua (result 4) and at Innisfail after three years (result 1), while in the second most reliable set of tests were the deck-on-grass after three and four years at

Innisfail (results 8,9) and the ground proximity test after four years at Innisfail (result 10). Also useful were the embedded tests at Rotorua painted (result 11) or unpainted (result 12). At the other end of the table, the most unreliable tests were the stake test at Innisfail after one year (result 44), trials in the AFSs at Clayton and Rotorua (results 36-39, 41-43), and Rotorua field exposures that were pre-inoculated (results 40,45).

These results suggest that tests positioned closer to the ground give more reliable results than raised tests, and those installed with artificial conditions applied (majority of time in the AFS or pre-inoculated) give less reliable results than natural full-time field exposures. The possible reason is that those tests close to the ground are likely to be colonized by a wider variety of fungal species due to ready inoculation from splashed soil (during rain), soil invertebrates bringing debris to the specimens and accumulated grass clippings from lawn mowing. Whereas, raised tests are in more exposed and harsher conditions for many fungal species (wider extremes in temperature and wood moisture contents) so that fewer species might become established. Indeed the peg test is slow probably because the small volume of its test specimens can dry out too quickly after wetting. When those fewer fungal species do become established in raised tests, they might then dominate that particular test frame and impose their peculiar tolerances and susceptibilities. The ground proximity test at Rotorua and especially Innisfail were fairly 'dirty' tests as ants, slaters, slugs and other invertebrates often bought a film of soil to the specimens (too much soil, and reliability for H3 preservatives can become a problem, as shown by the in-ground stake tests) and grass/weeds often grew through and between the bricks and specimens (Figures 55, 56). For the deck-on-grass test at Innisfail grass clippings especially, and some soil, accumulated within any recesses in the frames (Figure 46). A wider variety of decay types and fruiting bodies were sometimes seen in these tests than in raised tests. It is likely important that test specimens have similar amounts of debris associated with them (as was apparent in this project), and to randomise test specimen positions within the tests to minimise the impact of any localised effects (full randomisation not done in double layer or peg tests).

In comparison, the raised deck at Innisfail appeared to be dominated by perhaps one fungal species (Figure 67), which was identified as a species of *Heterotextus*, possibly *H. peziziformis* or *H. miltinus*. This genus is not particularly well known as wood decay fungi in the built environment, but was particularly savage on the azole treatment, whereas when this fungus had to compete with many other species deck-on-grass its dominance reduced so that azoles performed within the comparative order expected. Other examples are that the 'old' flat panel test at Innisfail (a 'raised' test) began as the fastest naturally inoculated H3 test (not pre-inoculated), as shown by water-treated *P. radiata* rating 3.2 after one year. But again, this 'old' frame was dominated by one particular brown rotting fungus that was later identified as *Fomitopsis lilacinogilva*. The rot box at Innisfail was the fastest H3 test of all as shown by the failure of CCA-treated *P. radiata* after two years, but here also the boxes appeared to be dominated by one fungal species that was copper-tolerant (to CCA), although it was very slow to affect AChQ-treated specimens perhaps due to the high quat loading in this treatment. This suspected copper-tolerant fungus was less able to influence the adjacent pre-inoculated rot boxes, because there was more competition from pre-inoculation with *Gloeophyllum abietinum* and *Perenniporia tephropora*. The rot boxes at Innisfail were placed on a large concrete pad rather than directly on the soil, so perhaps had some shielding (by means of distance) from the natural variety of inoculum that may have occurred if they had been placed on bare earth or grass. The double layer test at Innisfail was placed on grass, but then a large frame (with sides twice as high as in the ground proximity test) topped with shade cloth surrounded the test, effectively shielding it from grass clippings and wind-blown debris. There was also less infiltration amongst test specimens by soil invertebrates compared to the ground proximity test. A fungus particularly tolerant of AChQ appears to have become

established in the double layer test at Innisfail. Perhaps the double layer test would have given a more typical order of failure if there was no shade cloth cover.

Similarly, tests pre-inoculated with one or two laboratory test fungi gave results at odds to the average result, as their particular tolerances could dominate. Therefore at Rotorua, *O. placenta* was particularly destructive of the quarter-H3 azole retention and this capacity could not be tempered by competition from other fungi attempting to establish during field exposure, whether in pre-inoculated rot boxes placed on bare earth or in pre-inoculated embedded tests placed on raised frames.

Best tests at each field test site

At Innisfail, the most reliable and fastest tests, where the quarter-H3 CCA-treated *P. radiata* mean ratings were below 6.0, were the deck-on-grass and ground proximity tests. The embedded tests, whether painted or unpainted, were the best of the 'raised' tests, and a suggestion for improving their reliability would be to place them closer to the ground. The deck-on-grass and embedded test also gave the required result (CCA mean rating less than 6.0) after three years. The rot box was also fast, but too severe on CCA. Therefore, the recommendation for Innisfail would be to conduct deck-on-grass tests, or embedded tests that are 90-100 mm (thickness of bearers) from the soil. The ground proximity test is also useful. A risk (or perhaps an advantage) of near-to-ground tests at Innisfail is that termites may influence results. At Innisfail, H3 tests are located in the middle of a large mowed area of lawn, and are some 50 metres away from the nearest vegetation/forested area. Over the 15 years of H3 field testing conducted by CSIRO at this site, termites were found in another flat panel test only once. Termites did not affect the current test. Therefore, the distance that the boundary fence and rainforest is from the H3 tests specimens is beyond the foraging distance of the many termites species found in the Innisfail rainforest.

At Clayton in the field, where fewer test designs were placed, the embedded test was fastest (CCA mean rating 6.4) followed by the ground proximity test (CCA mean rating 7.6). The embedded test was surprisingly fast at Clayton, and it seems likely that a suitable preservative comparison could have been achieved if there was one more inspection (year 5) when the mean CCA rating would most likely be less than 6.0. The embedded test was not raised, but had been placed on a large concrete pad, so may have been even faster if placed on grass.

At Rotorua in the field, apart from the less reliable pre-inoculated tests, the lowest CCA rating obtained was 7.3 for the embedded painted test, followed by the ground proximity test (mean rating 7.6) and the embedded test (unpainted, mean rating 7.8). Again, the embedded tests may have been faster if placed nearer to the ground. It is noteworthy that Clayton had a lower rating for CCA of 6.4 in the embedded test, even though Rotorua has twice the rainfall. Perhaps this was due to the embedded test at Clayton being placed on a concrete pad, which was of greater benefit than being raised. The rot boxes at Rotorua were placed on the grass, and had more decay than those at Clayton which were on the concrete pad.

Comments on H3 testing and designs

Results from this project support the view that testing for new wood preservatives should include or start with pure culture bioassays in the laboratory. Then, the main fungal species attacking timbers in service in the built environment can be tested, along with their individual peculiar tolerances. In Australia, fungi commonly isolated from wood in service are routinely used in fungal bioassays (AWPC protocols), and can detect any unusual susceptibilities to this list of important fungi. Then, a field test could be conducted where frames are placed close to ground, to determine the likely 'average' performance under most circumstances relative to other preservatives.

There may be occasions when the results obtained by peculiar dominating fungi in the raised field tests, tests on large concrete pads, or pre-inoculated tests would be useful for fine-tuning the performance of a particular preservative. For example, if formulation variations of azoles were to be examined for improved performance, then a raised deck test at Innisfail, or a pre-inoculated test with *O. placenta*, would be warranted.

It is sometimes thought that the ground proximity test, especially in the tropics, can be more like a ground contact test than a proper H3 test. However, this project shows that the ground proximity test gave the correct relative order of failure for H3 timbers, unlike the in-ground stake test at Innisfail. It is often easier to obtain test samples that are sapwood only by cutting 200 x 35 x 35 mm rather than 200 x 75 x 25 mm specimens. There seems no special reason for excluding either size from the ground proximity test.

The embedded tests were orientated at a 45^{o} angle with the idea that more water might drain into the 'joint'. However, a vertical orientation would probably be just as effective, and then the frames would be easier to install and more frames could be stacked into the same area. At Rotorua the embedded test was slightly faster when painted (average rating of all means was 5.2) than unpainted (average rating of all means 6.4), perhaps due to increased water trapping by the paint coating. At Innisfail the embedded test was similar whether painted (average rating of all means 4.0) or unpainted (average rating of all means 3.9), as water was mostly not limiting in this wet environment. This project suggests that the embedded test could be improved by placing the frames on treated pine bearers 90-100 mm from the ground.

The rot boxes generally became too wet (Table 7). Indeed, test specimens often squirted water when jabbed with a knife. At Innisfail it seemed that one copper-tolerant brown rot fungal species was unusually able to tolerate such damp conditions, and then caused rapid decay by the two year inspection. At Clayton during the three year inspection, several thick plastic meshes were placed between the rows (producing ~5 mm gaps) to try and reduce water-logging. However, even this step was insufficient to encourage significant decay. It seems that at least one end of a test specimen should be exposed and able to wick moisture by drying, so that a moisture gradient can establish in the test specimen so that optimal moisture conditions will then occur somewhere along the specimen's length. Therefore, a better design for the rot box may be to remove the two long sides of the box, so that specimens are effectively cradled within a U-shaped frame rather than a four sided box.

The peg test showed some potential at Innisfail, although it was still the slowest test at this site. At Clayton no result was achieved after four years as all pegs were sound. If time was of less concern, the peg test could be improved by having for example 100 replicates of each

treatment. The pegs are readily available, and could be treated to a mean retention rather than weighing each peg. Then, a 'natural' range of wood performances that include some defects would occur (in other tests, only those specimens close to the desired retentions are tested). Inspection is quick, simply by opening and closing the peg, and could also provide some information on corrosiveness to the metal hinge.

Test specimens in the double layer test were often quite wet, especially at Innisfail, yet the test had useful rates of decay at both sites where it was installed (Innisfail and Rotorua). A frame was made so that shade cloth was above the test specimens, with the aim of retaining moisture to hasten decay. This frame may be useful in drier sites (such as if it had been installed at Clayton), but is not needed at Innisfail, and also may best be excluded at Rotorua. If shade cloth is used, it may be better to make a frame with open sides rather than full length boards that shield against soil debris that could otherwise accumulate amongst the test specimens. A potential risk with the double layer test is that test specimens are not more evenly randomised in the frame, that is, all replicates are placed together.

The raised and deck-on-grass tests were installed to provide a calibration between the more true-to-life 'raised' deck usage and the accelerated deck-on-grass (although decks close to ground are sometimes built). At Innisfail after four years the average of all mean ratings was 2.1 (about 82% destroyed) for deck-on-grass and 5.1 (about 38% destroyed) for raised deck. Also, the average for all mean ratings was 6.1 after two years for deck-on-grass and also after three years for raised deck. These results suggest the deck-on-grass suffers decay 30 to 50% faster than raised deck at Innisfail. At Rotorua after four years the average of all mean ratings was 7.3 (about 6% destroyed) for deck-on-grass and 7.9 (about 1% destroyed) for raised deck. Also, the average for all mean ratings was 7.8 after two years for deck-on-grass and 7.9 after four years for raised deck. Perhaps, these results support the view that deck-on-grass is 50% faster than raised deck; however, there is insufficient decay differentiation at this stage for reliable comparisons to be made at Rotorua.

Flat panel tests were often used by CSIRO in Australia, and appeared to give fairly reliable results (Table 20, Clayton result 5, Innisfail, result 16). At Innisfail this test usually takes 6-7 years before comparative results suitable for preservative registration can be achieved, and indeed the quarter-H3 CCA-treated *P. radiata* specimens still had a mean rating of 7.0 after four years at Innisfail. The flat panel test at Innisfail had half of the replicates placed on an old frame and then the mean rating was 6.4, and half on a new frame where the mean rating was 7.6. Therefore, flat panel test results can be accelerated by placing new tests on 'old' frames (frames where local fungi have already become established).

Conclusions

1. The relative order of test site severity was Innisfail (most severe), Rotorua AFS, Rotorua, Clayton AFS and Clayton (least severe). For the field tests, this sequence follows the same order as mean annual rainfall of 3600 mm (Innisfail), 1400 mm (Rotorua) and 700 mm (Clayton).
2. The only field test site where quarter-H3 CCA-treated *P. radiata* had reached a mean rating less than 6.0 in H3 'natural' tests (not pre-inoculated) was at Innisfail. At this site, the rot box achieved this threshold after two years, the deck-on-grass and embedded tests after three years, and the ground proximity, painted embedded and double layer tests after four years.
3. The slowest test at Innisfail was the peg test, and it failed to give a result at Clayton (all pegs were sound). The flat panel test was also amongst the slowest tests, but could be accelerated by placing new tests on old frames in which local fungi had already become established.
4. The most reliable tests, that followed same the relative order of failure as all tests at all field sites combined, were the deck-on-grass and ground proximity tests. The likely reason is that these tests are placed close to the ground where a wider range of fungal species can establish, rather than in 'raised' tests that provide harsher conditions and fewer fungi which can then dominate and impose their own peculiar tolerances upon the test. The most reliable 'raised' test was the embedded test.
5. Tests on 'ground' but still partially shielded from soil/grass debris also tended to give less reliable results and become dominated by fewer fungi. The rot boxes at Innisfail were on a large concrete pad (away from soil) and appeared to become dominated by a copper-tolerant brown rotting fungus that was too severe on CCA. The double layer test at Innisfail was enclosed on the sides by a tall frame built so that shade cloth could cover the test, and a fungus particularly severe on AChQ-treated specimens became established.
6. Other atypical results arose from tests pre-inoculated with laboratory fungi, especially at Rotorua where *Oligoporus placenta* was used. The in-ground stake tests, especially at Innisfail, gave an atypical relative order of failure to that found in H3 exposure. Trials in the AFSs at Clayton and Rotorua also tended to be less reliable at producing the typical order of failure found in natural field exposure.
7. At Rotorua, only the inoculated embedded test had reached a mean rating less than 6.0 for quarter-H3 CCA-treated *P. radiata*. In the Rotorua AFS, both pre-inoculated tests (embedded and rot box) and the embedded test (not pre-inoculated) gave mean ratings less than 6.0 after four years.
8. At Clayton, the most severe test of those installed was the embedded test, and it seemed likely that this test would achieve a result (CCA rating less than 6.0) after five years. In the Clayton AFS only the painted embedded test had reached a mean rating of less than 6.0 for quarter-H3 CCA-treated *P. radiata*.
9. The fastest in-ground stake trials occurred at Innisfail, followed by Rotorua AFS and Clayton AFS.
10. The raised deck at Innisfail, and the pre-inoculated (*O. placenta*) tests at Rotorua were particularly severe on quarter-H3 azole-treated *P. radiata*. Most of the decay in the raised deck at Innisfail appeared to be due to a species of *Heterotextus*.
11. The flat panel test on the old test frame at Innisfail was one of the fastest tests initially, but has slowed compared to most other tests at Innisfail. This frame appeared to be dominated by *Fomitopsis lilacinogilva*.

12. The rot box design often caused test specimens to become too wet for decay. However at Innisfail it was the fastest test, and more decay occurred in non-inoculated than pre-inoculated boxes, suggesting that pre-inoculation inhibited the establishment of more aggressive local fungal species.
13. Bing^{TM} testing is an acoustic method for detecting changes in MOE in flexure, and was able to detect decay or incipient decay earlier than could be detected by probing with a knife. This method could therefore be used to make assessments earlier than can be made using conventional 'pick testing'.
14. The most reliable and fastest tests to use are the deck-on-grass, ground proximity and embedded tests (painted or unpainted). Reliability can be improved by placing tests closer to grass or bare earth.
15. More unusual results occur in raised tests, which may be useful for testing formulation variations to those preservatives found to be unusually susceptible in certain test designs. Laboratory bioassays can also test against selected fungi, and utilise fungi that are ubiquitous and known to be relevant to the built environment.

Recommendations

It is recommended that the embedded (preferably placed near the ground) and ground proximity tests be included in the AWPC protocols. The deck-on-grass test is already in the protocols.

While some of the tests examined can produce the required results in 3-4 years at Innisfail, it would be prudent to run such tests for longer duration as this would inevitably improve accuracy and confidence in comparisons. Also, given the variation that can be obtained from different tests, it would also be useful to have results from at least two different test sites or tests when considering the efficacy of new wood preservatives.

Acknowledgements

We would like to thank Forest and Wood Products Australia, Osmose Australia and Arch Wood Protection for their support of funding towards this project, and Ian Simpson of Scion for his help during the latest Rotorua inspections. Jackie van der Waals of Scion also helped with the establishment and maintenance of the trials in New Zealand. We wish to acknowledge the encouragement and intellectual support lent to this project by the late Dr Mick Hedley.

Appendix 2: Four year inspection results for test specimens

Key:

PR = *Pinus radiata*
SG = Spotted gum (*Corymbia maculata*)

In the treatment column, q means quarter H3 retention.

In the retention % m/m or air dry density column, the result for:
SG none is air dry density in kg/m^3
PR water is air dry density in kg/m^3
AChQ is elemental copper % m/m oven dried wood
CCA is total active element of Cu + Cr + As % m/m oven dried wood
Azoles is total azoles % m/m oven dried wood
TBTN is elemental tin % m/m oven dried wood
HFK is HFK % m/m oven dried wood
Tan E is elemental copper plus tebuconazole % m/m oven dried wood
CuN is elemental copper % m/m oven dried wood
CC is Cu + Cr % m/m oven dried wood
Boron is elemental boron % m/m oven dried wood

Innisfail new frame flat panel installed 19-22 Nov 2007, inspected 3-4 Nov 2011
